Declaration

Ich erkläre mich damit einverstanden, dass die Zentrale Hochschulbibliothek Lübeck die elektronische Dissertation und die dazugehörigen Daten in Datennetzen zur öffentlichen Nutzung bereitstellt. Die Zentrale Hochschulbibliothek ist berechtigt, die elektronische Dissertation und dazugehörigen Daten an die Deutsche Nationalbibliothek weiterzugeben.

Falls persönliche Daten (Lebenslauf) in meiner Dissertation enthalten sind, bin ich damit einverstanden, dass diese von der Zentrale Hochschulbibliothek Lübeck und der Deutschen Nationalbibliothek maschinell gespeichert und zur öffentlichen Nutzung bereitgestellt werden.

I agree that the Central University Library Lübeck makes the electronic dissertation and the associated data available in data networks for public use. The Central University Library is authorized to forward the electronic dissertation and associated data to the German National Library.

If personal data (curriculum vitae) are included in my dissertation, I agree that they may be stored by machine by the Central University Library Lübeck and the German National Library and made available for public use.

Sincerely,

Lindsay Ruth Sonnenkalb

1. Abstract

The causative agents of tuberculosis (TB), bacteria of the *Mycobacterium tuberculosis* complex (Mtb), continue to be among the deadliest pathogens worldwide killing about 1.4 million people per year. Infections with Mtb strains mainly affect the lungs and require a minimum of six months antibiotic treatment consisting of four drugs, even increasing to over 20 months treatment in some patients with multidrug resistant (MDR, resistance against isoniazid and rifampicin) strains. Such treatment durations cause a long-term selection pressure on the bacteria that can rapidly develop resistance if antibiotic regimens are not effective. Recent pharmacodynamic studies also demonstrated that not all drugs in combination therapy reach target sites of infection, e.g. lung granulomas, at a therapeutic level. Thus, even with a fully functional antibiotic regimen, Mtb bacteria may survive and evolve in evolutionary niches with sub-inhibitory drug concentrations. How these microenvironments contribute to the evolution of antibiotic resistance in a patient, and if sub-inhibitory concentrations can select for resistant bacterial subpopulation with low fitness costs is currently not well understood in Mtb bacterial infections.

To address these questions, this study investigated resistance evolution in serial isolates from a patient under MDR-TB treatment by whole genome sequencing (WGS), and developed an *in vitro* evolution model to study the selection of resistant subpopulation at low drug doses, i.e. below the minimum inhibitory concentrations (MICs) of major MDR-TB antibiotics. The resistant clones obtained were investigated for resistance mechanisms by WGS, and for selected clones the mutant selection window (MSW) was defined in which resistant strains outcompete their susceptible counterparts. These experiments were carried out with moxifloxacin (MXF), the new anti-TB drug bedaquiline (BDQ), and the repurposed drug clofazimine (CFZ). All mutations selected *in vitro* were combined with mutations found in clinical strains, including a large-scale strain collection (CRYPTIC cohort) to eventually build up an improved mutation catalogue for WGS-based molecular resistance prediction.

First, this study examined the intra-patient resistance evolution of a single infectious strain throughout a complex 13-year treatment period. Thirteen bacterial isolates were analyzed by WGS, and compared to phenotypic drug susceptibility testing (DST) and the clinical treatment history. Several phases of monotherapy or with no active drugs were detected, correlating with the emergence of heteroresistant subpopulations. Indeed, the rise and fixation of 7 resistance-associated mutations over treatment was observed, in a strain which harbored 8 pre-existing resistance mutations.

To further define the impact of sub-inhibitory drug exposure on resistance development and to quantify the mutant selection window, an *in vitro* evolution model based on long-term exposure of the Mtb

reference strain H37Rv to drug concentrations below the MIC was established. After exposure to MFX, BDQ, or CFZ, resistant subpopulations increased over time, already at concentrations as low as 1:16 the MIC. In fact, all sub-inhibitory concentrations tested, selected for numerous clonal subpopulations with a diverse set of resistance associated variants defined by population WGS and selection of single colony clones. Mutation diversity was large for all drugs, and a mutant strain collection was established including 356 selected and characterized clones, harboring one of 79 unique resistance-associated variants. To develop a resistance mutation catalogue for BDQ and CFZ, *in vitro* data was combined with an extensive literature search and data from a large patient cohort (consisting of over 14,000 strains) resulting in an interpretation database with more than 150 variants. Interestingly, thirteen clones with a BDQ and/or CFZ resistant phenotype were found to have a 2.5 Mb inversion, which cut through the gene *Rv0678*, and was categorized as a novel resistance mechanism. Finally, competition experiments showed that the most commonly selected MFX and BDQ clones harboring a mutation in either *gyrA*, *gyrB*, *atpE*, or *Rv0678*, had little to no fitness loss in direct growth completion experiments with the wild-type ancestor clone. Further, growth of these clones was measured in the automated MGIT system at various sub-inhibitory concentrations, which showed that resistance mutations have a selective advantage to the wild-type under a weak selection pressure far below the MIC, pointing to a wide mutant selection window.

In conclusion, the analyses performed in this thesis confirmed that the microevolution of Mtb strains in TB patients under therapy is a highly dynamic process of competing heteroresistant populations that is driven by poor treatment regimens. The developed *in vitro* evolution model under sub-inhibitory drug concentrations has a high potential to study resistance evolution and define resistance mechanisms as they generate clones with a wide spectrum of mutations, including clinically relevant mutations. Similar models could be used to investigate new drug compounds before coming to market; but also, to explore the effect of alternative treatment models such as synergy and antagonistic drug combinations, or drug-cycling on resistance development. The mutation catalogue established far extends current knowledge on BDQ/CFZ genomics for resistance prediction, to be used for personalized medicine of MDR-TB patients. It became also clear that the majority of mutations in *Rv0678* confer cross-resistance to BDQ and CFZ, and that CFZ exposure selects for mutant populations resistant to BDQ. The *in vitro* models employed demonstrated for the first time that resistant Mtb subpopulations can be selected in an environment with a weak selection pressure far below the MIC. This has important implications for personalized MDR-TB therapies suggesting that therapeutic drug monitoring, MIC determination, and bacterial mutation profiles can improve therapy outcomes in the most difficult to treat MDR-TB patients.

1. Zusammenfassung

Mit jährlich etwa 1,4 Millionen Todesfällen gehören die Erreger der Tuberkulose (TB), Bakterien des *Mycobacterium tuberculosis*-Komplex (Mtbk), nach wie vor zu den tödlichsten Krankheitserregern weltweit. Die TB wird mindestens sechs Monate mit vier Medikamenten behandelt; bei multiresistenten (MDR, Resistenz gegen Isoniazid und Rifampicin) Fällen kann die Behandlungsdauer sogar 20 Monate und mehr betragen. Diese langwierige Behandlung führt zu einem hohen Selektionsdruck auf die Tuberkulosebakterien, was z.B. im Falle von ineffektiven Therapieregimen schnell zur Selektion von Resistenzen führen kann. Pharmakodynamische Studien haben zudem gezeigt, dass nicht alle Medikamente in der Kombinationstherapie die Infektionsherde, z. B. die Lungengranulome, in ausreichender Konzentration erreichen. Somit können Mtbk-Stämme selbst bei einer generell wirksamen Antibiotikatherapie in diesen „evolutionären Nischen“ mit sub-inhibitorischen Antibiotikakonzentrationen überleben und neue Resistenzen entwickeln. Welchen Einfluss das auf die Entwicklung von Antibiotikaresistenzen unter Therapiebedingungen hat und ob sub-inhibitorische Konzentrationen eine Selektion von resistenten Stämmen mit geringen Fitnesskosten bewirken können ist bei TB nicht ausreichend geklärt.

Um diese Fragen zu beantworten, wurde in dieser Arbeit die Resistenzentwicklung von seriellen Isolaten eines MDR-TB Patienten mittels Gesamtgenomsequenzierung („whole genome sequencing“, WGS) untersucht. Des Weiteren wurde ein *in vitro* Evolutionsmodell zur Analyse der Selektion von resistenten Klonen bei sub-inhibitorischen Antibiotikakonzentrationen, d. h. unterhalb der minimalen Hemmkonzentrationen (MHK), entwickelt. Die resistenten Klone wurden mittels WGS auf Resistenzmechanismen untersucht und für ausgewählte Klone wurde das so genannte „mutant selection window“ (MSW) definiert, in dem resistente Stämme einen Selektionsvorteil gegenüber sensiblen Wildtyp-Stämmen haben. Die Selektions-Experimente wurden mit drei MDR-TB Medikamenten, Moxifloxacin (MFX), dem neuen anti-TB Antibiotikum Bedaquilin (BDQ) und dem Antibiotikum Clofazimin (CFZ) durchgeführt. Zur Erstellung eines verbesserten Mutationskatalog für die WGS-basierte molekulare Resistenzvorhersage wurden die *in vitro* selektionierten Mutationen mit Resistenz-vermittelnden Mutationen von Mtbk-Stämmen aus der großen CRyPTIC Stammsammlung und mit Daten aus einer umfassenden Literatursuche kombiniert.

In dieser Arbeit wurde zunächst die Resistenzentwicklung eines einzelnen MDR-Mtbk-Stammes (Dreizehn klinische Isolate) im Verlauf von 13 Jahren MDR-TB Therapie untersucht. Mehrere Phasen mit Monotherapie oder sogar ohne effektive Antibiotika korrelierten mit dem Auftreten von heteroresistenter Bakterien Subpopulationen und späterer Fixierung der Mutationen. So erwarb der initial achtfach resistente Stamm im Verlauf der Behandlung sieben neue Antibiotikaresistenzen.

Um die Auswirkungen von niedrigen Antibiotikakonzentrationen auf die Resistenzentwicklung genauer zu untersuchen wurde ein *in vitro* Evolutionsmodell etabliert, in dem der Mtbk-Referenzstamm (H37Rv) bei sub-inhibitorischen Antibiotika Konzentrationen (unterhalb der MHK) passagiert („evolviert“) wurde. Bei allen verwendeten Antibiotika (MFX, BDQ und CFZ) wurden resistente Subpopulationen bereits bei Konzentrationen von 1:16 der MHK selektioniert. Die WGS Analyse von Selektionsklonen und Bakterienpopulationen (alle Zellen von einer Platte) zeigte, dass bereits bei geringen Antibiotikakonzentrationen eine Vielzahl von Klonen mit unterschiedlichen Resistenz-vermittelnden Mutationen selektioniert wird. Insgesamt wurden 356 Selektionsklone untersucht und Klone mit 79 unterschiedliche Resistenz-vermittelnde Mutationen phänotypisch charakterisiert. Weiter Untersuchungen des „mutant selection window“ (MSW) ergaben das ausgewählter Klone mit Mutationen in *gyrA*, *gyrB*, *atpE* und *Rv0678* selbst bei schwachem Selektionsdruck weit unterhalb der MHK einen Selektionsvorteil gegenüber dem Wildtyp haben, was auf eine breite MSW hindeutet.

Diese Mutationsdaten aus den *in vitro* Experimenten wurden dann mit Daten aus einer großen Patientenkohorte (mehr als 14.000 Stämmen) und mit publizierten BDQ und CFZ Resistenz-vermittelnden Mutationen kombiniert. Die etablierte Interpretationsdatenbank umfasst mehr als 150 Mutationen. Bei 13 resistenten Selektionsmutanten wurde eine 2,5 Mb-Inversion im Genom detektiert, die das Gen *Rv0678* betrifft und als neuartiger Resistenzmechanismus eingestuft wurde. Kompetitions-Experimente zeigten, dass die am häufigsten selektionierten MFX und BDQ-resistenten Klone im Vergleich mit dem Wildtyp Stamm nur geringe bis gar keine Fitnessverluste hatten.

Zusammenfassend bestätigen die durchgeführten Analysen, dass die Mikroevolution von Mtbk-Stämmen bei ineffektiven Antibiotikatherapien ein hochdynamischer Prozess mit konkurrierender heteroresistenter Subpopulationen ist. Das entwickelte *in vitro* Evolutionsmodell ist hervorragenden für die Untersuchung von Resistenzmechanismen geeignet und könnte in Zukunft zur Analyse Resistenz-vermittelnde Mutationen für neue Antibiotika vor der Markteinführung genutzt werden. In ähnlichen Modellen sollen in Zukunft auch alternative Kombinationstherapien untersucht werden, die Synergien und Antagonismen zwischen verschiedenen Antibiotika berücksichtigen. Der entwickelte Mutationskatalog verbessert die Möglichkeiten für die Pathogenom basierte Resistenzdiagnostik und besonders durch das verbesserte Verständnis von BDQ und CFZ Resistenzmechanismen. So wurden die hier generierten Daten bereits bei der personalisierten Behandlung von MDR-TB Patienten eingesetzt. Die erhobenen Daten bestätigten, dass Mutationen in *Rv0678* eine Kreuzresistenz zwischen BDQ und CFZ vermitteln. Die durchgeführten Experimente zeigten zum ersten Mal, dass resistente Subpopulationen unter schwachem Selektionsdruck weit unterhalb der MHK selektiert werden können. Dies hat wichtige Auswirkungen auf die personalisierte MDR-TB-Therapie und legt nahe, dass therapeutische Arzneimittelüberwachung, MHK-Bestimmung und

die Analyse bakterieller Mutationsprofile die Therapieergebnisse bei MDR-TB-Patienten verbessern können.

“But I would like to sound one note of warning. Penicillin is to all intents and purposes non-poisonous so there is no need to worry about giving an overdose and poisoning the patient. There may be a danger, though, in underdosage. It is not difficult to make microbes resistant to penicillin in the laboratory by exposing them to concentrations not sufficient to kill them, and the same thing has occasionally happened in the body.”

- Alexander Fleming, Nobel Lecture, December 11, 1945

2. Introduction

2.1 Tuberculosis Epidemiology

It is conservatively estimated that bacteria of the *Mycobacterium tuberculosis* complex (Mtb) have been causing tuberculosis (TB) in humans for over 40,000 to 75,000 years [1], [2]. TB mainly manifests as a disease of the lungs, but can also affect almost any other tissue in the body. In 1882, Robert Koch first discovered that “tubercle bacilli” were responsible for TB diseases, which later earned him the Nobel Prize in medicine in 1905 [3]. At this turn of the century the leading cause of death in humans were communicable infections, such as wound infections, diphtheria, cholera, or TB. Over 120 years later, the leading cause of death today has shifted to ailments such as heart disease and cancer, yet TB still remains the deadliest disease caused by a single pathogen, only surpassed by major pandemics like the 1918 Flu and SARS-CoV-2 outbreak in 2020 [4]–[6].

According to the World Health Organization (WHO), in 2020 alone, bacteria of the Mtb were responsible for 1.5 million deaths worldwide, with over 10 million newly reported cases [4]. The areas with the highest TB incidence include Southern and Eastern Asia (especially India, Indonesia, and the Philippines) as well as Sub-Saharan Africa (with exceptionally high incidence rates in South Africa and the Central African Republic) (Figure 2.1A) [7]. Fortunately, there has been a steady decrease in human immunodeficiency virus (HIV)-positive TB-cases, yet infection control efforts have failed every milestone target (Figure 2.1B).

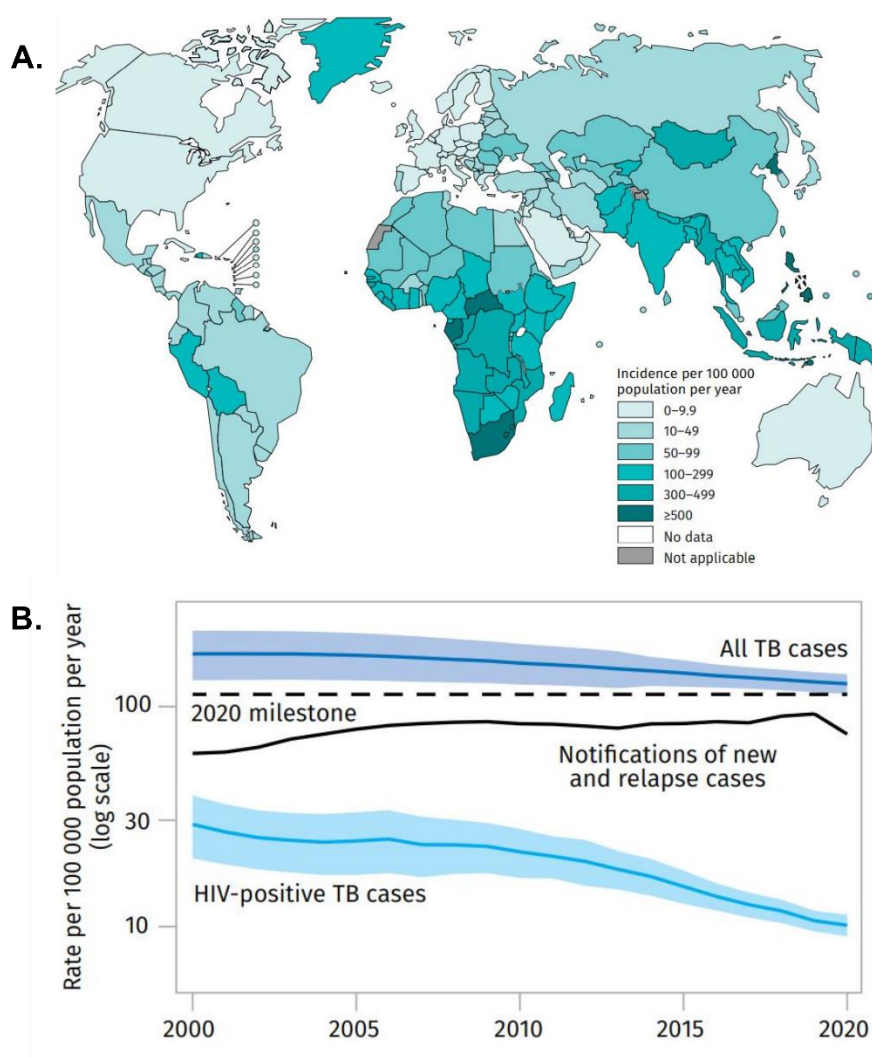

Figure 2.1: Estimated tuberculosis incidence rates per 100,000 in 2020. (A) Global incidence rate colored by country; higher incidence indicated by darker coloration. (B) Global trends of all tuberculosis cases (dark blue), notified new cases (black), and HIV-positive TB cases (light blue); 95% confidence intervals indicated as shaded areas. Images obtained from World Health Organization - Global tuberculosis report 2021 [4].

Nearly one third of the total world population is estimated to be infected with an Mtb strain, yet only 5-10% of those enter a symptomatic state, known as active-TB [8]. Active infection, defined as the presentation of clinical symptoms such as cough, weight loss, and night sweats; is required for the bacteria to be transmitted. It is not fully clear why a low rate of those infected progress to active disease, although there are several risk factors such as a weak immune system due to immunocompromising pathogens like HIV, or comorbidities including (but not limited to): malnourishment (poverty), diabetes, cancer, or substance (tobacco/drug/alcohol) abuse [4], [9]. Nevertheless, TB disease in most high incidence settings is linked to malnutrition and poverty [4].

For those who develop active TB, it can take months, years, even decades after initial infection for symptoms to arise [10]. It is also possible to be re-infected after successful treatment [11]–[13]. When treatment is not successful, patients can suffer a “relapse” or “recurrent” infection, which usually occurs within the 12 months following treatment conclusion [14], [15]. It is unclear why some patients suffer from recurrent infection, although it is likely linked to high bacterial load or poor diagnosis [16].

It has been confirmed that resistant Mtb strains have been transmitted throughout human populations for decades [17], [18]. Resistance acquisition in Mtb strains is at the forefront of the antibiotic resistance crisis, in which TB accounts for one-third of all resistant bacterial deaths worldwide [7]. Although the highest number of TB cases consolidates in Africa and East Asia (Figure 2.1), most rifampicin resistant (RR) and MDR cases occur in Eastern Europe, especially countries of the former Soviet Union (Figure 2.2). MDR-TB is defined as being resistant to RIF and INH, the two most effective anti-TB drugs [7].

Figure 2.2: Percentage of rifampicin or multi-drug resistant tuberculosis among newly-reported tuberculosis cases worldwide. Percentage of resistant tuberculosis cases colored by country; higher incidence indicated by darker coloration. Images obtained from World Health Organization - Global tuberculosis report 2020 [7].

Large-scale global strategies which enhance supportive systems and research initiatives are needed in order to stop the spread of TB. As outlined by the WHO End TB Strategy, the aid needed for TB eradication is to: “Achieve universal health coverage, including financial risk protection, access to quality essential health-care services and access to safe, effective, quality and affordable essential medicines and vaccines” [7].

2.2 Tuberculosis treatment

The current, worldwide treatment success rate for susceptible TB infections is around 85%; in low income, high incidence countries treatment success ranges between 50 and 90% [7]. While there are many potential causes of treatment failure, non-compliance to treatment and poor drug regimens are foremost important [19], [20]. Patient non-compliance is a pitfall for treating any bacterial infection, and implies that the patient arbitrarily stopped taking their medication before treatment conclusion, or were taking their medication inappropriately (skipping doses for example). Due to the fact that even a susceptible TB infection takes at least 4 to 6 months to treat, it is not uncommon for patients to discontinue therapy once symptoms subside. A recent study in India determined that up to 25% of patients discontinue therapy before reaching 5 months of treatment [21]. Inappropriate drug regimens are often prescribed due to unknown drug resistance, or dwindling treatment options in highly resistant cases. Other factors associated with treatment failure include: relapse, over-active patient metabolism, and pathological factors which impede drug delivery as highlighted in recent pharmacokinetics and pharmacodynamic studies [22]–[24].

Several strategies have been implemented to defeat these treatment limitations such as extensive and rapid drug susceptibility testing (DST), centralized treatment methods, and precision medicine [25], [26]. One strategy developed by the WHO to combat this problem was “DOTS”, or Directly Observed Treatment, Short-course (short course referring to a six- to eight-month therapy). The DOTS program was shown effective in high burden countries, not only because it included consistent anti-TB drug administration by trained personnel, but also patient education, standardized treatment protocols, and treatment follow-up [27].

Although there have been major technological advances in medicine in the past decade, a protective and effective pulmonary TB vaccine has yet to be established. It has been 80 years since the only TB vaccine, *M. bovis* bacillus Calmette-Guérin (BCG) vaccine, has been employed, and still it is only conclusively protective against the exceptionally lethal TB meningitis, in young children and infants [28]. Currently, there are two promising vaccines in phase III clinical trials. VPM1002, a recombinant BCG whole-cell vaccine, for preventative and therapeutic application; and the MIP vaccine, a BCG vaccine booster composed of heat inactivated *Mycobacterium indicus pranii* [29]–[32]. Until an effective vaccine is authorized and administered, the main (and most effective) strategy to fight Mtb bacteria is through robust antibiotic treatment.

2.3 Drug resistance in *Mycobacterium tuberculosis* complex strains

In 1943, just a few years after the implementation of the first antibiotic penicillin, the first anti-TB drug was discovered by A. Schatz, E. Bugle, and S. Waksman [33]. Streptomycin (SM), a protein synthesis inhibitor, was administered on a wide-scale after proving efficacious in a Guinea pig model, in which 70% of the control group succumbed to infection compared to only 8% of the treated group [34]–[37]. Concurrently, para-aminosalicylic acid (PAS) was being developed and came to market as drug resistance was already being described in patients who received SM mono-therapy [38], [39]. Early experiments and trials proved that giving these drugs in combination was most effective, and from that time on, it was advised never to treat TB with a single compound [40]–[42].

Combination therapy is a hallmark and obligatory aspect in the treatment of TB. Since the golden era of antibiotic discovery/development and today, some 25+ TB antibiotics have been included in treatment regimen combinations, based on efficacy and safety (Table 2.1). As set by the WHO, the standard treatment regimen of a susceptible TB infection requires six months of antibiotics; four months of INH, RIF, ethambutol (EMB), and pyrazinamide (PZA) plus two months of continued INH and RIF [43]. As resistance to the most effective drugs arise, the drug regimen is modified to include more toxic drugs and can increase treatment duration from nine months to two or more years.

Table 2.1 Overview of the most important anti-tuberculosis drugs

Antibiotics	Abbreviation	Resistance-associated genes	Mode of action
Rifampicin [†]	RIF	<i>rpoB</i> [44], <i>ponA</i> [45]	Blocks bacterial transcription by binding RNA polymerase β subunit
Isoniazid [†]	INH	<i>katG</i> [46], <i>inhA</i> [47], <i>fabG1</i> promotor [48]	Inhibits mycolic acid synthesis (cell-wall component)
Ethambutol [†]	EMB	<i>embC</i> [49], <i>embA</i> , <i>embB</i> [50], [51]	Inhibits arabinoglycan synthesis (cell-wall component)
Pyrazinamide [†]	PZA	<i>pncA</i> [52], <i>rpsA</i> [53]	Inhibits membrane transport and fatty acid synthesis
Streptomycin	SM	<i>rrs</i> [54], <i>rpsL</i> [55], <i>gidB</i> [56]	Inhibits protein synthesis by binding 16S rRNA subunit
Fluoroquinolones ^α	FQ	<i>gyrA</i> , <i>gyrB</i> [57], [58]	Inhibits DNA gyrase through binding of type II topoisomerase.
Amikacin	AMK	<i>rrs</i> [59]	Disrupts protein synthesis by binding 30S ribosomal subunit
Kanamycin	KAN	<i>rrs</i> [60], <i>eis</i> [61], <i>whiB7</i> [62]	Disrupts protein synthesis by binding 30S ribosomal subunit
Capreomycin	CPR	<i>rrs</i> [59], <i>tlyA</i> [63]	Disrupts protein synthesis by binding to the 70S ribosomal subunit
Ethionamide/ prothionamide	ETH/ PTH	<i>ethA</i> [64], <i>ethR</i> [65], <i>fabG1</i> promotor [48], <i>inhA</i> [47]	Inhibits mycolic acid synthesis (cell-wall component)
Para-Aminosalicylic Acid	PAS	<i>ribD</i> promotor [66], <i>thyA</i> [67], <i>folC</i> [66]	Inhibits folic acid synthesis
Linezolid	LZD	<i>rpIC</i> [68], <i>rrl</i> [69]	Inhibits protein synthesis
Cycloserine/ Terizidone	CS/ TRD	<i>alr</i> [70], <i>ddl</i> [71], <i>ald</i> [72]	Inhibits peptidoglycan synthesis (cell-wall component)
Clofazimine	CFZ	<i>Rv0678</i> [73], <i>pepQ</i> [74]	Inhibits cell growth, binds bacterial DNA (may also bind bacterial potassium transporter)
Bedaquiline	BDQ	<i>atpE</i> [75], <i>Rv0678</i> [76], <i>pepQ</i> [77]	ATP synthase inhibitor
Delamanid/ Pretomanid	DLM/ PRT	<i>fbiA/fbiB/fbiC</i> [78], <i>ddn</i> [79], <i>fgd1</i> [79]	Inhibits mycolic acid biosynthesis (cell-wall component)

[†]First-line antibiotics, multi-drug resistance (MDR) defined as resistance to both INH and RIF

^αclass of antibiotics which includes ofloxacin (OFX), moxifloxacin (MXF), gatifloxacin (GFX), and levofloxacin^β (LFX)

Still, the emergence and spread of resistant Mtb strains continued over the last years. There were about half a million estimated RR cases in 2019, approximately 78% of which were MDR. Even with amended WHO guidelines to treat these critical patients, treatment success is reduced to 57% in RR/MDR cases [7]. Further resistant cases are classified as extensively-drug resistant (XDR), defined as an MDR-Mtb strain with resistance to a fluoroquinolone (FQ) such as levofloxacin (LFX) or moxifloxacin (MFX), plus one other group A drug such as bedaquiline (BDQ) or linezolid (LZD) (Table 2.2) [80].

Table 2.2 World Health Organization drug grouping and treatment recommendation for multi-drug resistant tuberculosis regimens

Groups	Compound/drug
Group A: Include all three	Levofloxacin or moxifloxacin Bedaquiline Linezolid
Group B: Add one of both to treatment	Clofazimine Cycloserine or terizidone
Group C: Add when drugs from Group A and B are not applicable	Ethambutol Delamanid Pyrazinamide Imipenem-cilastatin or meropenem Amikacin or Streptomycin Ethionamide or prothionamide <i>P</i> -aminosalicylic Acid

It is clear that resistance can arise within a patient under treatment, but recent studies using DNA-sequencing technologies to evaluate clinical isolates derived from a single patient, showed that this is a dynamic process [81], [82]. This process often includes heterogeneous populations consisting of multiple variants which arise spontaneously and compete until one is ultimately selected, and then becomes fixed in the population [81], [83]–[87].

2.4 Tuberculosis diagnostics

Fast and accurate diagnosis of a bacterial infection with an Mtb strain is critical for prompt and successful treatment, as well as for tracking and reducing transmission. Current diagnostic tests fall into four main categories: diagnosis of disease, DST, detection of exposure, and monitoring treatment progress. Although

there have been major advances in diagnostics by immunological and molecular assays, confirmation of active infection still relies on older methods such as microscopy, primary isolation, and culturing [88].

The WHO recommends molecular assays as initial testing for TB infection, which will likely become the new gold standard in TB diagnostics [89]. The most widely used tests employed in diagnostic laboratories are polymerase-chain reaction (PCR) based assays such as GeneXpert® Ultra (Cepheid, USA) and Truenat™ MTB (Molbio Diagnostics, India), which include detection of TB and screening for RIF resistance. Line-probe assays such as the Hain GenoType MTBDRplus (Hain Lifescience, Germany) and Nipro NTM+MDRTB Detection Kit (Nipro, Japan) are also used in initial diagnosis, but can detect further resistances to the most important drugs (RIF, INH, and FQs). However, line-probe assays are more difficult to perform than the nearly, fully automated PCR based assays.

Currently, the gold standard for diagnosing antibiotic resistance is phenotypic DST. These diagnostics can be performed using microtiter broth assays by observing growth inhibition through color changing and fluorescence dyes such as alamarBlue™ or resazurin (resazurin emission microtiter assay, REMA), and growth inhibition on solid agar plates supplemented with high concentrations of the drug [89]. For diagnostic laboratories with more infrastructure, the mycobacterium growth indicator tube (MGIT) BD BACTECH™ (USA) automated system is used, which measures growth through oxygen consumption. While these assays are more sensitive and can detect a wide range of resistance, they are incredibly time consuming taking 10 days for liquid culture systems, and from 3-6 weeks on solid media [90].

With advancements in next generation sequencing (NGS) technology, plus a major reduction in their cost, whole genome sequencing (WGS) may become the new gold-standard for genomic DST. Genomic DST is accomplished by comparing the NGS data of a particular clinical Mtb strain to a reference genome, and identifying genomic variants of known drug resistance-associated variations. In a landmark paper in the New England Journal of Medicine, the authors concluded that “WGS can now characterize profiles of susceptibility to first-line anti-tuberculosis drugs with a degree of accuracy sufficient for clinical use” [91]. NGS gives the option to not only evaluate all possible resistances through analyzing variants in all resistance-associated genes, but also to detect heterogeneous populations (clonal subpopulations and mixed infections) [92], [93]. Unfortunately, NGS is currently not yet in widespread use due to high infrastructure cost and required training for data interpretation (which will be overcome by web-based tools for data interpretation such as PhyResSE) [94], [95]. An additional pitfall of genomic DST is the difficulty in predicting level of resistance, due to the wide range of mutations and the phenotypic variability of Mtb strains [96].

A major effort is also being made to improve treatment progress monitoring which can enhance short-term therapy strategies and overall cure rates. In most settings, treatment progress is monitored by observation of clinical symptoms, but does not always predict the treatment success/failure. To better predict early treatment failures and overall outcomes, efforts are being made to identify biological markers. These markers are biological measurements of the host or microbe, performed as immunological and molecular assays, which might be less biased and more sensitive [97]–[99].

Taken together, TB diagnostics has advanced significantly over the last years, as a large-scale effort by private and publicly funded entities are being made to develop and distribute diagnostic tools to bolster treatment and reduce resistance development in populations which need them most [100].

2.5 Pathology of tuberculosis infection

TB disease mainly manifests as a pulmonary infection, but Mtb bacteria have the capacity to infect nearly any cell, and thus, can spread to other regions of the body [101]. When the bacilli are inhaled into the lungs of a new host, a complex interplay of innate and adaptive immune responses is triggered, which defines the pathology of the disease [102].

The primary cellular hosts of Mtb bacteria are alveolar macrophages. When the bacteria are phagocytosed, the macrophage must quickly kill them through autophagy, or the bacteria may be able to prevent phagosome maturation, and eventually escape into the cellular cytosol [103], [104]. After infection, the macrophage will begin recruiting other immune cells such as neutrophils, dendritic cells, T-cells, B-cells, and other types of macrophages, in an attempt to clear the pathogen [105]. In the case that the bacteria are not eliminated, these different cell types work together to form a granuloma, a structure which can contain the viable bacteria and prevent further dissemination throughout the body [106].

The granuloma is a hallmark feature of TB disease which varies in composition and size. The formation of these dynamic structures requires an adaptive immune response, in which T-cells produce an abundance of cytokines (most importantly tumor necrosis factor alpha and interferon gamma) that aid in the recruitment of other immune cells, activate macrophage killing, and stimulate the production of collagen [105], [107]. The collagen produced by fibroblasts not only helps in tissue repair, but creates the fibrous cuff lining the granuloma, which walls off and contains the bacteria [105], [108]. Although granulomas are important for bacterial containment, they can also allow the bacilli to persist in their necrotic center, also called the caseum [109], [110]. Not only does the granuloma prevent contact with immune cells, but also decreases the capacity of several antibiotics to reach the bacteria at therapeutic concentrations [111]–

[114]. Many anti-TB drugs accumulate in the fibrous-cuff and host-cellular regions of the granuloma, with a few that are capable of reaching and diffusing across the caseum (Figure 2.3; Appendix A, Table A.1). The antibiotics which can reach the caseum, can exhibit a major reduction in concentration level. When the cellular granuloma matures and expands it can reach the lumen, or airway, causing an abscess and the formation of a cavity (Figure 2.3) [115].

Figure 2.3: Capacity of anti-tuberculosis drugs to accumulate throughout the granuloma and lung cavitation. A number of pharmacokinetic and pharmacodynamic studies investigating human and rabbit material, have found that not all antibiotics are capable of penetrating the granuloma and/or cavitation. Here are the highlighted areas where the different drugs have been found to accumulate at a therapeutic level (at or above the critical concentration needed for Mtbc bacterial killing). CS/TRD, CPR, AMK, LZD, KAN, DLM anti-TB drugs not included. Extended data table of high, medium, and low drug accumulation throughout granuloma and cavitation zones in Appendix A, Table A.1. Data from [111]–[114], [116]–[118].

AMK: amikacin, BDQ: bedaquiline, CFZ: clofazimine, CPR: capreomycin, CS: cycloserine, EMB: ethambutol, ETH: ethionamide, FQ: fluoroquinolone, INH: isoniazid, MFQ: moxifloxacin, PAS: para-aminosalicylic acid, PZA: pyrazinamide, RIF: rifampicin.

Lung cavitation is another important pathological feature of TB disease, and one of the leading risk factors linked to recurrent infection [16], [119]. Lung cavitations are especially beneficial to the bacteria, as they allow for an oxygen rich environment with a direct path to the airway for transmission. These structures further protect the bacteria from most anti-TB drugs due to poor vascularization and low pharmacokinetic potential [116]–[118]. Sub-inhibitory drug concentrations have been measured throughout the lung cavity for most drugs, as they must diffuse from the blood vessel into normal lung tissue, past activated immune

cells, through the fibrous cuff of the cavity, into the necrotic center full of cell debris and to the cavity surface where the Mtb bacilli also form a biofilm of replicating and non-replicating bacteria (Figure 2.3) [115].

All-in-all, there are four patterns of drug distribution throughout these pathological lesions, rapid and homogenous (INH, PZA, and LZD), rapid and heterogeneous with high accumulation in the cellular layer versus the caseum (FQs), slow distribution including gradual accumulation in the caseum (RIF), and rapid distribution mainly accumulating in the cellular layer with poor caseum diffusion (BDQ or clofazimine; CFZ) (Figure 2.3) [120]. It is likely that these pockets of low, below MIC, drug distribution could play a role in intra-patient antibiotic resistance evolution, although a clear connection has yet to be established.

2.6 Mechanisms of antibiotic resistance evolution

Understanding the mode and conditions under which drug resistances arise, is paramount in the fight to cure the world of TB. As described by Alexander Fleming in his Nobel Prize Lecture, it was observed for the first discovered antibiotic - penicillin, that microbes can develop resistance when exposed to sub-inhibitory drug concentrations [121]. While he was correct in this statement, it was not yet known, that resistance alleles arise stochastically in bacteria, and that a selection pressure is required for those alleles to proliferate (high or low concentrations of antibiotics, interspecies and allele competition, etc.).

Evolutionary theory describes the rise of resistant variants in bacteria via horizontal gene transfer (by plasmids or transposons), the recombination of external DNA into the chromosome, or by other changes of the chromosome by gene rearrangements, single nucleotide polymorphisms (SNPs), insertions/deletions (indels), or by full gene deletion/duplication [122]. Selection pressures, such as antibiotic/antiviral exposure, lack of nutrients, competition with other species, or DNA damage (such as host induced oxidative stress), influence the mutation rates of bacteria [123]–[126]. Mutation rate can be defined as the probability of a mutation to arise in a bacterial clone [127]–[129]. Antibiotic resistance rates can be measured *in vitro* through experimentation such as the Luria-Delbrück fluctuation assay, which measures the rise/appearance of an alternative allele over time, in the presence or absence of a selection pressure [127]. One caveat to such methods, is that the number of mutant cells is being counted and not the number of mutational events i.e. mutation frequency. Hence, quantification of mutation frequency is not easily accomplished, and with this method in particular you would not detect all mutation events.

Antibiotics can increase mutation rates through triggering stress activated pathways such as the “SOS pathway”, leading to an error prone-alternative polymerase activation (e.g. increased expression in the

nucleotide excision repair proteins like *recA*) [126]. Other stress pathways include regulatory changes in gene expression mediated by induced genes like the alternative sigma factor *RpoS* [130], or by enhancing the production of DNA damaging reactive oxygen species (particularly affected by quinolones, aminoglycosides, and beta-lactams) [131]. Furthermore, different antibiotics can lead to different mutation rates, aka mutability, based on their target's function (translation, transcription, or protein synthesis for example) or number of independent targets. In other words, mutability is the probability a mutation will give rise to a resistant phenotype which is dependent on structure and number of genes which can produce a resistant phenotype (Figure 2.4). For example, if the bacteria can become resistant from a single mutation in gene A, and the mutability of gene A is 10^{-7} , the mutation rate for the drug is 10^{-7} . If the bacteria required a mutation in gene A or gene B to become resistant, and the mutability of gene A is 10^{-7} and gene B is also 10^{-7} , then the mutation rate for the drug is 2×10^{-7} . This is seen in prodrugs, where a mutation in the drug activating enzyme gene or the direct target gene, results in resistance. On the other hand, if the drug has two direct targets, then a mutation in both gene A and gene B is required for resistance and the mutation rate is 10^{-14} . Therefore, the most effective drugs have a very low mutability rate, enhanced by having multiple modes of action (or direct targets).

Mutability of gene A = 10^{-7}

Mutability of gene B = 10^{-7}

Mutation rates:

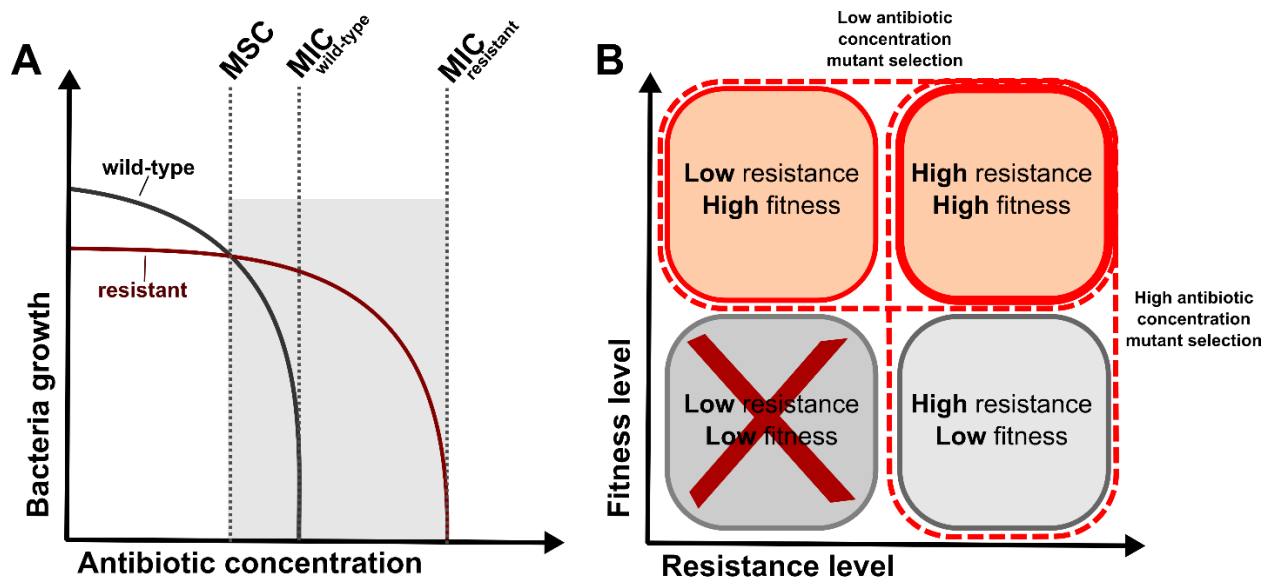

- Only to gene A = 10^{-7}
- Either gene A or gene B = $10^{-7} + 10^{-7} = 2 \times 10^{-7}$
- Both gene A and gene B = $10^{-7} * 10^{-7} = 10^{-14}$

Figure 2.4 Mutation rate calculations based on mutability of resistance-associated genes. Calculation of mutation rates based on gene mutability in a clonal population, when gene A and gene B both have a hypothetical mutation rate of 10^{-7} .

When exploring and understanding antibiotic resistance evolution to particular anti-TB drugs, an important concept to consider is the mutant selection window (MSW). The MSW is defined as the drug concentration range in which a resistance allele is selected and outperforms the genetically wild-type (gWT) population (Figure 2.5A). The minimum selection concentration is defined as the lowest drug concentration required in order for the resistant mutation to be selected, i.e. the weakest selection pressure needed. This is especially important as mutations generally compromise bacterial fitness; therefore, some amount of antibiotic is required in order to give resistant subpopulations an advantage

over the wild-type population. Both mutant and gWT populations can only tolerate an antibiotic to a certain concentration, known as the MIC.

It has been hypothesized that by exposing a heteroresistant bacterial population to a weak selection pressure, drug concentrations between the minimum selection concentration and the wild-type MIC, the competition with the surviving wild-type population would facilitate the selection of more fit resistant variants (Figure 2.5B). Due to the heterogeneous phenotype of variants in different genes/loci, the size of MSW can fluctuate between variants, to the same antibiotic.

Adapted from Andersson & Hughes *et al* 2012

Figure 2.5 The mutant selection window and fitness/resistance level selection. (A) The mutant selection window (MSW) is defined as the drug concentration range in which resistance conferring mutations are selected and enriched, for any given mutation this is between the minimum selection concentration (MSC) and the minimum inhibitory concentration (MIC) of the resistant mutant (gray colored zone). Within the MSW is the MIC of the wild-type (or susceptible ancestor), generally (but not always) the concentration in which the resistant mutant begins to outgrow the wild-type. (B) Fitness level and resistance level are important indicators of the potential survival of certain mutations. Mutations which lower the fitness of the resistant clone are less likely to be selected due to competition with a heterogenous population (including the susceptible ancestor). Adapted from Andersson and Hughes *et al.* 2012 [132].

Within the last 15 years, studies pioneered by Gullberg *et al.* 2011 and Liu *et al.* 2011, found that low concentration drug exposure, in some cases as low as 100-fold below the MIC, selected and enriched antibiotic resistant bacterial populations [133], [134]. These studies included bacterial species such as

Escherichia coli and *Salmonella enterica*, which have highly diverse genomes and dynamic mobile gene mechanisms. So far, similar evolutionary experiments have not been conducted with strains of the Mtb, where previous studies applied a high-selection pressure environment, i.e. drug concentrations at or above the MIC, or oxidative stress like H₂O₂ [135]–[137]. However, as outlined in the previous section, due to the complex pathology of TB disease, there are a number of intra-patient niches where the bacteria could be exposed to sub-inhibitory drug concentrations, thus potentially fostering the emergence of resistant subpopulations even in virtually effective combination therapy. Understanding the MSW in relation to pharmacokinetics and the spatial distribution of drugs used in combination therapy is crucial to design the most effective treatment regimens especially for RR-, MDR-, and XDR-TB cases.

2.7 Applying evolutionary medicine principles and precision medicine to fight tuberculosis

In bacteria of the Mtb, resistance principally arises due to variations in the chromosome, observed as SNPs and either large or small insertions or deletions (indels). There have also been reports of large-scale gene rearrangement events, but these are rare [138]–[140]. This microevolution, or clonal nature, of Mtb strains is further evident by their highly stable genome. The largest difference between any two Mtb strains is about 2,000 SNPs (out of 4.4 million base pairs), therefore over 99% of the genetic material between all strains in the complex is conserved [2]. This genome stability of Mtb bacteria makes them perfect organisms for WGS analysis, and a prime candidate for genomic DST.

An up and coming field which aims to integrate evolutionary principles to better understand, prevent, and treat disease is evolutionary medicine. In the case of treating infectious diseases, evolutionary medicine aims to understand and use pathogen evolution to better treat and mitigate pathogen adaptation to therapeutics [141]. In this scope, when developing treatment guidelines, one should consider: pathogen virulence, the role and management of the microbiome, immune system evasion & suppression by the pathogen, their rapid adaptation to antibiotics and how alternative therapies could reduce resistance evolution.

Precision medicine then takes evolutionary medicine to the next level by considering the patient and strain data in order to optimize a treatment strategy tailored to the individual patient [26]. WGS is integral in this method as it allows for detailed epidemiological analysis for outbreak tracing, as well as rapid resistance diagnostics by predicting drug resistance profiles based on a mutation catalogue. These catalogues are developed from extensive datasets including patient and *in vitro* derived isolate genome sequences

coupled with phenotypic DST results (i.e. MIC) [140], [142]. From these catalogues, one can determine drug regimens by predicting the likelihood in which a genomic point mutation can lead to high-level resistance (discontinue drug), low-level resistance (adjust drug dosage), or whether the mutation is benign (continue normal treatment) [26], [143]. Such efforts have unparalleled clinical value, as they accelerate diagnosis and reduce treatment failure through improved, better informed treatment designs.

Overall knowledge of TB infection, transmission, and pathology has greatly increased over the last 40 years, but evolutionary mechanisms of intra-patient resistance acquisition are not well understood. Still, there are important gaps in current knowledge on resistance development in relation to patient characteristics; e.g. granuloma structures, the MSW for different drugs/variants, and further factors that may boost mutation frequencies of *Mtbc* strains in the patient. There is still virtually no experimental data available which focuses on the consequences of long-term antibiotic exposure, a situation which is required for successful tuberculosis treatment.

Study objectives

As outlined above, several aspects of resistance evolution in clinical Mtb strains are currently not well defined. To address these gaps, the main aim of this thesis is to elucidate mechanisms of resistance acquisition in clinical Mtb strains.

Main goals were:

- Elucidate factors which enhance intra-patient resistance evolution in a failing MDR treatment
- Develop and explore the drug resistance evolution of Mtb bacteria in a long-term evolutionary model
 - using a prolonged weak selection pressure.
- Define the MSW for important group A & B drugs used for treatment of MDR-TB patients
- Validate the genomic variants found in the weak selection pressure evolution model by using data from a large patient strain collection
- Provide an extended mutation catalogue for BDQ and CFZ

3.1 Materials

3.1.1 Consumables

Product	Order number	Company
8-Lid chain, flat	65.989.002	Sarstedt
96-well plate, flat bottom, sterile	833.924	Sarstedt
96-well plate, U-shape bottom, sterile	833.925	Sarstedt
Adhesive film for microplates	60941-062	VWR
AMPure® PB Beads	100-265-900	PacBio

3.1.8 Solution and media preparation

Solution/Media	Procedure
0.83% Saline Solution	Dissolve 8.3 g NaCl in 1000 mL distilled H ₂ O, autoclave, store in fridge
1:10 Methylene Blue Solution	Dilute 5 mL methylene blue in 45 mL distilled H ₂ O, store at room temperature
10% sodium dodecyl sulfate (SDS)	Add 100 g SDS to 1000 mL distilled H ₂ O, store room temperature
10mg/mL Lysozyme	Dissolve 100 mg lysozyme in 10 mL DEPC water, store at -20°
10mM Tris-HCl Buffer pH 8.5	Dissolve 1,576 g Tris HCl in 1000 mL distilled H ₂ O, set to pH 8.5, store room temperature
20% Tween⁸⁰	Combine 20 mL Tween ⁸⁰ with 80 mL distilled H ₂ O, stir with metal rod until completely dissolved, pass through 0.2 µm syringe filter, store at room temperature - protect from direct light
5M NaCl	Dissolve 146.1 g NaCl in 500 mL distilled H ₂ O, store at room temperature
70% ethanol	Combine 70 mL 100% ethanol with 30 mL distilled H ₂ O, store at room temperature
7H10 agar plates	Dissolve 19 g 7H10 powder and 5 mL glycerol in 900 mL distilled H ₂ O, autoclave, add 100 mL bovine serum, transfer 20-25 mL to petri dishes, allow time to solidify, store in refrigerator
7H11 agar plates	Dissolve 19 g 7H11 powder and 5 mL glycerol in 900 mL distilled H ₂ O, autoclave, add 100 mL OADC, transfer 20-25 mL to petri dishes, allow time to solidify, store in refrigerator
7H9 medium (broth)	Dissolve 4.7 g 7H9 powder and 2 mL glycerol in 900mL distilled H ₂ O, autoclave, add 2.5 mL 20% Tween ⁸⁰ ; add 10% OADC shortly before use, store at fridge
BDQ selective media	1 liter 7H11, cool to ~56°C, add 50 µL or 25 µL bedaquiline stock (5mg/mL BDQ concentrated), transfer 20-25 mL to petri dishes, allow time to solidify, store in refrigerator no more than 2 days
CFZ selective media	1 liter 7H11, cool to ~56°C, add 100 µL clofazimine stock (5mg/mL CFZ concentrated), transfer 20-25 mL to petri dishes, allow time to solidify, store in refrigerator no more than 2 days
Chloroform/Isoamyl alcohol (24:1)	Combine 48 mL chloroform with 2mL isoamyl alcohol, store at room temperature

CTAB/NaCl	Dissolve 4.1 g NaCl in 80 mL distilled H ₂ O, while stirring add 10 g N-Cetyl-N,N,N- trimethylammonium-bromide (CTAB), heat solution to 65°C to dissolve, store at room temperature
MFX selective media	1 liter 7H10 agar, cool to ~56°C, add 100µl moxifloxacin stock (5mg/mL MFX concentrated), transfer 20-25 mL to petri dishes, allow time to solidify, store in refrigerator no more than 7 days
Resazurin	Weigh resazurin salt and transfer to a tube. for every 1 mg of resazurin salt add 10 mL water, mix well by vortex, let dissolve for 5 minutes, pass through 0.5 µm syringe filter, protect from light, use immediately.
Water + 0.05% Tween80	Autoclave 1000 mL distilled H ₂ O, add 2.5 mL 20% Tween80, store in fridge

3.2 Methods

3.2.1 Basic laboratory procedures

3.2.1.1 Colony forming unit plating and counting

Colony forming units (CFU) refers to the number of bacterial colonies which grow on solid agar, and are an indication of bacterial quantity at time of plating, 1 CFU = 1 bacterial cell. CFU plating was performed on 7H10 agar plates. Bacteria grown in liquid culture were first passed through an 18 G cannula four times. The culture was then diluted up to 1:10⁷. This was achieved by conducting 1:10 dilutions in a 96-well plate, starting by transferring 25 µL of bacterial culture into 225 µL water with 0.05% Tween⁸⁰. All subsequent dilutions were conducted by transferring 25 µL into 225 µL, pipette tips were changed between each dilution. Next, 100 µL from each dilution was transferred to half of a 7H10 agar plate, and spread until dry with a sterile loop. Dilutions were performed in technical triplicates; each triplicate was plated one time. Once plates were dried, they were inverted (agar on top) and sealed in plastic bags (20 plates per bag). All plates were incubated at 37°C for at least 21 days. After incubation colonies were counted and bacterial numbers were calculated.

$$n \text{ colonies} * \text{dilution factor} * 10 = \frac{CFU}{mL}$$

3.2.1.2 Colony forming unit plating on selective media plates (antibiotic supplemented)

In order to quantify the number of mutants which arose in a population over time, CFU plating was also conducted on 7H10 (for MFX) or 7H11 (for BDQ and CFZ) agar plates. CFU dilutions were performed like normal CFU plating (Methods 3.2.1.2), except 100-200 µL of diluted culture was spread across the entire agar plate. Additionally, a five times concentrated dilution was plated of each culture. This was achieved by transferring 10 mL of culture to a screw cap tube, then centrifuged for 10 minutes at 4,000 g at room temperature. The supernatant was then discarded, and the bacterial pellet was resuspended in 2 mL water + 0.05% Tween⁸⁰. After plates were sealed and incubated at 37°C for 21.28 days, mutant colonies were counted and quantified as a ratio - mutant per million CFU:

$$\frac{\text{Mutant } CFU/mL}{\text{Total } CFU/mL} * 10^6 = \text{Mutant per million CFU}$$

3.2.1.3 Optical density measurements

Turbidity of bacterial cultures was measured by optical density at 600 nm in cell density meter (spectrophotometer). Spectrophotometer was calibrated with culturing media (7H9), 1 mL was added to a cuvette, covered with a single-use lid, and read as the blank. Bacterial cultures were then measured in 1 mL aliquots in cuvette tubes, covered with single-use lids.

3.2.1.4 Ziehl-Neelson Staining - Acid fast staining

Acid fast staining was performed to check for fungal or bacterial combinations throughout experiments. First, 10 µl of bacterial culture was transferred to a microscopic slide and spread around in a small area using a pipette. Once the slide was fully dried, it was passed through a Bunsen burner flame 5 times (bottom side, opposite bacteria). Slide was left to cool for some seconds and passed through the flame another 5 times, then passed through the flame one additional time on the bacteria side of the slide. Slides were then taken out of the biosafety level 3 lab and taken to the biosafety level 2 chemical hood.

Slides were stained by first covering the slide completely with carbolic fuchsin solution and heated over a flame until it started to steam (do not boil). Slides were allowed to cool slightly, then heated again by flame until steaming. This was done a total of three times. After heating the slide was left to cool for ten minutes. Carbolic fuchsin solution was then rinsed off by dipping the slide in distilled water. The slide was then dipped in HCl-ethanol 3% for histology. The slide was again washed in distilled water. Next, the slide was immersed in 1:10 diluted methylene blue solution for 1 minute. Finally, the slide was washed by dipping in distilled water. After the slide dried, observation was conducted by oil immersion microscopy. If only pink rods were observed no contamination was determined. If blue forms are observed (bacilli or cocci) culture was likely contaminated.

3.2.1.5 Contamination exclusion by blood agar plating

Blood agar plating was performed to check if cultures were contaminated with fungi or other bacterial species. About 50-100µl of experimental culture was dropped on blood agar plates. Plates were incubated at 37°C for at least one week. If growth was observed, culture was likely contaminated.

3.2.1.6 Brain-heart-infusion and lysogeny broth culturing

Additional checks for exogenous bacterial/fungal species in experimental cultures were performed by culturing in additional broths. Ten mL brain-heart-infusion and 10 mL lysogeny broth were added to separate tubes. Depending on bacterial density, 50µl-100µL of experimental culture was transferred to each tube. Tubes were sealed and incubated at 37°C for up to two weeks, and checked for growth after 7 and 14 days. If cloudy cultures were observed, experimental culture was considered contaminated, and checked again by acid fast staining.

3.2.1.7 Isolation of genomic DNA from patient isolates

Bacterial samples which were originally recovered from sputum samples were removed from -80°C freezer and grown on Löwenstein-Jensen medium at 37°C until growth became viable. Next, bacterial colonies were scraped and transferred to 1.5 mL screw cap tubes containing 400 µl distilled water. Bacteria was then deactivated (killed) by incubation in an 80°C water bath, for 20 minutes. DNA isolation was conducted by CTAB procedure.

3.2.1.8 Deactivation of *Mycobacterium tuberculosis* strains from liquid and solid media

Mtbc bacteria was grown in 7H9 media, and 5-10 mL was transferred to a 15 mL screw-cap tube. The sample was then centrifuged for 10 minutes at 4,000 g, at room temperature. The supernatant was discarded by pouring, then pellet was resuspended in 400 µL distilled water and transferred to 1.5 mL screw cap tube. Screw cap tubes were closed, and incubated in an 80°C water bath for 20 minutes for deactivation (killing) of bacteria. Samples were then safe to remove from biosafety level 3 lab.

From solid agar, bacteria were scraped from plates with sterile loops and transferred to a 1.5 mL screw cap tube containing 400 µL distilled water. Screw cap tubes were closed, and incubated in an 80°C water bath for 20 minutes for deactivation (killing) of bacteria. Samples were then safe to remove from biosafety level 3 lab.

3.2.1.9 CTAB DNA isolation

First, tubes containing deactivated (killed) bacteria were centrifuged for 3 minutes at 12,000 relative centrifugal force (rcf), the supernatant was discarded and the pellet was resuspended in 400 μ L 5nM Tris/HCl, pH 8.5. Next, 50 μ L of 10 mg/mL lysozyme was added, the sample was vortexed for 5 seconds, and incubated at least 1 hour (or overnight) in a 37°C water bath.

Next, 75 μ L of 10% SDS/proteinase K mix (5 μ L Proteinase K (10 mg/mL) + 70 μ L 10% SDS) was added to sample, vortexed shortly, and incubated for 10 minutes at 65°C. Then, 100 μ L 5M NaCl and 100 μ L CTAB/NaCl mix (prewarmed at 65°C) was added. Sample was vortexed until the liquid contents became white, and was then incubated for 10 minutes in a 65°C water bath. After, about 750 μ L chloroform/isoamyl alcohol (24:1) mix was added and the sample was vortexed 10 seconds, then centrifuge 15 minutes at 12,000 rcf at room temperature. The aqueous supernatant was then transferred to a new tube and 0.6 volume (450 μ L) isopropanol was added. The sample was carefully mixed (by inverting tube several times) and incubated for 30 minutes at -20°C.

Samples were then centrifuged for 15 minutes at 12,000 rcf, the supernatant was discarded and remaining liquid was dabbed on a paper towel. Next, 500 μ L of cold 70% ethanol was added, samples were centrifuged again at 12,000 rcf for 5 minutes. The ethanol was discarded and the remaining liquid was dabbed on a paper towel. Samples were again centrifuged for 5 minutes at 12,000 rcf, and remaining liquid was carefully removed with pipette (careful not to disturb the DNA pellet). The DNA pellet was then dried in a heating block for 20 minutes at 60°C. Finally, the DNA pellet was resuspended in 40-80 μ L water or 5nM Tris/HCl, pH8.5 buffer. Samples were again incubated in a heating block for 20 minutes at 60°C to help dissolve the DNA pellet. Tubes were then vortexed, liquid was spun down by short (3 seconds) centrifugation, then concentration and purity were measured in Spectrophotometer DS-11 FX.

3.2.2 Evolutionary experimental model

3.2.2.1 Sub-minimum inhibitory concentration evolution model

Mycobacterium tuberculosis complex (Mtb) strain H37Rv frozen stock was taken from -80°C freezer and thawed to room temperature. Bacterial stock was passed through 18 G cannula 10 times, and 0.5 – 1.0 mL was transferred to 60 mL Nalgene® culture bottle containing 2 mL 7H9 medium. Culture was incubated at 37°C standing. After 1 – 2 days incubation, an additional 10 - 20mL 7H9 medium was added. Optical density was measured at 600nm (OD) daily, and additional 7H9 media was added after an OD of 0.2 was reached,

which increased the culture volume to at least 40 mL. Once bacteria reached an OD of 0.4 – 0.6, bacteria were passaged to experimental culture bottles containing sub-MIC antibiotics (Table 3.1). The final bacterial concentration was calculated to an OD of 0.05 in 50 mL 7H9 medium (supplemented with antibiotic or no antibiotic for control culture). Experimental culture bottles were then incubated at 37° standing. At the start of each experiment the sub-culture was also analyzed by CFU plating on 7H10 agar plates and selective media plates. Some of the original culture was saved for DNA isolation.

Table 3.1: Antibiotic concentrations examined in evolutionary experiments. Final concentrations in mg/L in 50 mL 7H9 medium.

Antibiotic	MIC	1:2 MIC	1:4 MIC	1:8 MIC	1:16 MIC	1:32 MIC	Control
Moxifloxacin	0.12 mg/L	0.06 mg/L	0.03 mg/L	0.015 mg/L	0.008 mg/L	NA	0.0 mg/L
Bedaquiline	NA	0.06 mg/L	0.03 mg/L	0.015 mg/L	0.008 mg/L	0.004 mg/L	0.0 mg/L
Clofazimine	NA	0.25 mg/L	0.12 mg/L	0.06 mg/L	0.03 mg/L	NA	0.0 mg/L

MIC – minimum inhibitory concentration, NA – not applicable

The OD of the experimental cultures was measured daily. On day two, the experimental cultures were transferred to a shake plate set to a speed of 50 rcf. On day four, all experimental cultures were passaged to new culture bottles, with the bacterial culture concentration again adjusted to OD 0.05 in 50 mL 7H9 medium, and antibiotic was added (Table 3.1). A total of five bacterial passages were conducted for each experiment, passage 1 - day 4, passage 2 - day 8, passage 3 - day 12, passage 4 - day 16, and passage 5 - day 20.

After passages 1, 3, and 5, experimental cultures were:

- Quantified by CFU plating
- Drug resistant mutant population was quantified by CFU plating on antibiotic supplemented plates
- Samples were taken for DNA analysis
- Backup stocks were made – 1 mL aliquot of culture, plus two 1 mL aliquots of 5x condensed culture
- Blood agar sterility checks were performed on all experimental cultures

After passaged 2 and 4:

- Samples were taken for DNA analysis
- Backup stocks were made – 1 mL aliquot of culture, plus two 1 mL aliquots of 5x condensed culture
- Blood agar sterility checks were performed on all experimental cultures

3.2.2.2 Re-plating of experimental cultures

It was necessary to repeat CFU plating on selective media plates due to:

- Plate contamination (when plates were made, during storage, or incubation)
- Over growth of colonies (mutant plating was not always diluted enough)
- Further investigation (e.g. experiments conducted with CFZ were later decided to be plated on BDQ plates; Results 4.2.3)

Backup culture stocks (which were frozen after each passage) were taken from -80°C freezer and thawed to room temperature. Bacteria was then passed through an 18 G cannula four times, and diluted or further plated on selective media plates. Blood agar sterility checks were performed. Leftover stocks were marked each time they were thawed and again stored in -80°C freezer.

3.2.2.3 Mutant isolation from selective media plates

After 21 – 35 days of growth on selective agar plates, mutant colonies were isolated as either single colonies (for single mutation selection), or multiple colonies (for total population deep sequencing).

First, a single colony was removed from the agar plate with a sterile loop (noted size and morphology of colonies), and transferred to a 1.5 mL tube with 1 mL culture medium. It was then passed through an 18 G cannula ten times to break up clumps. The sample was then split between two Nalgene® culture bottles (0.5 mL each), or all was transferred to one Nalgene® bottle (only done with CFZ experiments) containing 2 mL 7H9 medium. Cultures were incubated standing, at 37°C, for 1-2 weeks. Once the culture bottle appeared cloudy (OD of 0.2-0.6), 15 mL 7H9 was added. OD was measured daily, once OD reached 0.4 to 0.8, two 1 mL aliquots were made and stored in -80°C freezer. A sample was also taken for DNA isolation and WGS analysis. Sterility of culture was checked by spot plating on blood agar plates.

Mutant isolation for total population deep sequencing was conducted by scraping all remaining colonies from selective agar plates and transferring them to 1.5 mL screw cap tubes, containing 400 μ L water. Each experimental condition was grouped separately (by experiment, passage, and drug concentration exposure). No sub-culturing was done. These bacteria were directly heat killed as previously described and DNA isolated by CTAB method.

3.2.3 Phenotypic assays

3.2.3.1 Resazurin emission microtiter assay – minimum inhibitory concentration testing

MIC testing of mutants isolated from evolutionary experiments were tested using REMA. A sub-culture was starting from frozen stocks (100 μ l) or from the Nalgene® bottle in which mutants were first grown. Bacteria were cultured in 7H9, and when an OD of 0.2-0.8 was achieved, a MIC test was started. One day prior to starting the test, cultures were checked for contamination by plating on blood agar.

Plates were prepared by diluting antibiotics in 7H9 media and transferring 100 μ l to a flat bottom 96-well plate. All plates included a positive control (well containing no antibiotic) and a negative control (7H9 media only) (Figure 3.1).

Figure 3.1 Resazurin emission microtiter assay set-up. Four bacteria strains were seeded in duplicates per plate. Each column contained a different drug concentration. Positive control wells were exposed to no antibiotic (0.0 mg/L) and negative controls were the blanks (only 7H9; column 9). Fluorescence was measured in a Synergy 2 plate reader and interpreted visually, as positive growth (purple/pink) or inhibited growth (blue). The lowest concentration which inhibited growth (blue well) was considered the minimum inhibitory concentration (MIC).

Next, bacterial sub-cultures were diluted to an OD of 0.3 ± 0.02 , and 0.5 mL was transferred to a new tube containing 9.5 mL 7H9 to achieve a 1:20 dilution. Bacteria were mixed evenly by inverting the tube or vortexing. Next, 100 μ L of bacterial suspension was added to appropriate wells of 96-well plate containing 100 μ L of 7H9 with or without antibiotics, using a multi-stepper pipette (Figure 3.1). All drug concentrations were tested in duplicates. The gWT ancestor strain was included in every test.

Plates were then sealed with adhesive film for microtiter plates, and stored in sealed boxes. Wet paper towels were also placed in boxes to reduce evaporation. Plates were incubated at 37° standing for 6-9 days. After incubation 30 μ L resazurin was added to each well. Plates incubated at 37°, overnight. Finally, the plates were measured in Synergy 2 plate reader, absorbance was measured at 570 nm, and fluorescence was measured at 544/590 nm. Photographs were taken of plates before they were discarded.

3.2.3.3 Mycobacterium growth indicator tube assay – drug susceptibility testing

MGIT MIC testing was performed by personnel at the National Reference Center for Mycobacterium Borstel. First, frozen bacterial stocks were thawed and 100 μ L was transferred to Löwenstein-Jensen solid agar, and incubated for three weeks at 37°. MGIT tubes were prepared using BACTEC™ MGIT™ 960 SIRE Kit. Colonies were removed from agar plates using sterile loops and transferred to 2 mL 0.83% saline solution. Colonies were homogenized using sterile glass sticks and allowed to settle for 10 min. Bacterial suspension was adjusted to a McFarland standard of 0.5 using 0.83% saline solution. From this suspension, a 1:5 dilution in 0.83% saline solution was performed. Then 0.5 mL was added to MGIT tubes which were supplemented with 0.8 mL SIRE supplement and 100 μ L antibiotic. A bacterial growth control was included by diluting to a McFarland standard of 0.5 by 1:500. Drug concentrations tested were 0.5, 1.0, and 2.0 mg/L for BDQ; 0.5, 1.0, and 2.0 mg/L for CFZ; 0.03, 0.06, and 0.12 mg/L for delamanid (DLM); and 0.5, 1.0, and 2.0 mg/L for LZD. Bacteria was considered resistant if a growth unit of 400 was reached before the growth control. An H37Rv gWT strain was not included in this test.

3.2.3.4 Mycobacterium growth indicator tube – mutant selection window

Sub-cultures were first started from frozen bacterial stocks. After stocks were thawed, 1 mL was added to the Nalgene® bottle with 10 mL 7H9. Cultures were incubated at 37°C standing. After two days, 5-10 mL

7H9 was added and cultures were incubated at 37°C on a shake plate at 50 rcf. Once cultures reached an OD >0.5, cultures were diluted to a McFarland standard of 1.0 (OD of 0.08-0.1). A second 1:5 dilution was done, and 0.5 mL was added to MGIT tubes supplemented with 0.8 mL OADC, and 100 µL antibiotics (or no antibiotic). A growth control was included by diluting to a McFarland standard by 1:500, and 0.5 mL was added to MGIT tubes supplemented with 0.8 mL OADC only. Experiments were carried out as biological duplicates or triplicates for all conditions (including growth control). MGIT tubes were loaded into BD Bactec™ MGIT and hourly measurements were taken for 15 days. Time to positivity was measured as hours or days until the tube fluorescence signal reached 400 units.

3.2.3.5 Fitness experiments – allele competition

Sub-cultures of the gWT ancestor and mutant clones were started from frozen bacterial stocks. After stocks were thawed, 1 mL was added to a Nalgene® bottle with 10 mL 7H9. Cultures were incubated at 37°C standing. After two days, 10-30 mL 7H9 was added and cultures were incubated at 37°C on a shake plate at 50 rcf. Once cultures reach an OD >0.5 culture was transferred to a roller bottle containing 100 mL 7H9. A 50:50 mixture of the gWT ancestor strain and one mutant clone was achieved by transferring culture to a roller bottle adjusted to a final concentration of 0.01 OD of each (OD 0.02 total). Biological triplicates were made of each, and CFU plating of sub-cultures were performed. Bottles were incubated at 37°C on a roller-bottle system, rolling at a motor voltage of 15 volts.

After seven days of incubation, 1 mL of culture was transferred to a new roller bottle containing 100 mL fresh 7H9. Roller bottles were again incubated for 7 days, then the experiment was concluded. Back-up culture stocks were made, transferring 1 mL culture to 1.5 mL screw cap tubes, and stored at -80°C. A 10mL culture sample was taken for DNA analysis.

Results were represented as changes in allele frequency. The starting allele frequency (F_i) was calculated from the initial CFU (i) of the starting inoculum (sub-culture inoculums from mutant stocks with the variant at 100% frequency). The final frequency of the mutant (M) allele and gWT allele were defined by WGS, M_{FF} and gWT_{FF} respectively. Fitness was indicated by change in allele frequency.

CFU inoculum calculation:

$$\frac{M_{CFU} * mL}{\frac{mL}{100}} = M_{CFU_i} \qquad \frac{gWT_{CFU} * mL}{\frac{mL}{100}} = gWT_{CFU_i}$$

Starting frequency of gWT and mutant alleles:

$$\frac{M_{CFUi}}{(M_{CFUi})(WT_{CFUi})} = M_{Fi}(\%) \quad 100\% - M_{Fi} = gWT_{Fi}$$

$$\text{Allele Frequency change of Mutant} = M_{Ff} - M_{Fi}$$

$$\text{Allele Frequency change of gWT} = gWT_{Ff} - gWT_{Fi}$$

Statistics calculated as non-parametric Kruskal-Wallis chi-squared test using R studio software (Appendix E).

3.2.4 Genotypic and Computational Analysis

3.2.4.1 Next generation sequencing

All DNA samples collected from *in vitro* experiments and MDR-TB case study (Results 4.1), were sequenced at Research Center Borstel. CTAB method was used to isolate DNA and libraries were prepared using Nextera-XT kits, performed according to manufacturer instructions. Quality of DNA and NGS libraries were verified on Fragment Analyzer using Standard Sensitivity NGS Fragment Analysis kits, according to manufacturer instructions. Samples were sequenced on NextSeq 500. Normal samples were loaded once onto the flow cell, deep sequenced samples were loaded three times.

NGS conducted on CRyPTIC samples was carried out by 14 independent laboratories, and data was collected for analysis by the group of Prof. Philip W. Fowler, Oxford University; and shared as excel files.

3.2.4.2 Genomic analysis

Analysis was performed using the bioinformatics pipeline MTBseq [146]. The pipeline was customized to run at “Low-Frequency Mode”, which excluded variant call thresholds of the standard pipeline output, and included all alternative allele calls. Variant tables were then manually filtered dependent on experiment using Microsoft® Excel. Low-frequency variants included in the MDR-TB patient case report (Results 4.1) were verified using binoSNP software [92].

Clinical strain sequences which were shared by CRyPTIC were analyzed using the Clockwork pipeline (<https://github.com/iqbal-lab-org/clockwork>), and the graph-based adjudication tool Minos ([Minos, https://github.com/iqbal-lab-org/minos](https://github.com/iqbal-lab-org/minos)) to create a final variant output file.

3.2.4.3 PacBio® sequencing

Genomic DNA was isolated using the CTAB method from bacteria in 7H9 culture. Libraries were prepared using SMRTbell® Express Template prep Kit 2.0 and SMRTbell® Enzyme Clean Up Kit according to manufacturer's "Procedure & Checklist - Preparing Multiplexed Microbial Libraries Using SMRTbell® Express Template Prep Kit 2.0". Primers were then added to libraries using Sequel II Primer v4 and Sequel II Binding Kit 2.0 according to "Loading and Pre-extension Recommendations for Sequel® System - Quick Reference Card". Samples were analyzed using SMRT® Link software according to "SMRT Link User Guide - Sequel® Systems" version 10. Dr. Christian Utpatel processed these samples and aided in computation analysis.

3.2.3.2 Minimum inhibitory concentration testing of patient strains

MIC testing of Mtb isolates collected by Comprehensive Resistance Prediction for Tuberculosis: an International Consortium (CRyPTIC) partners, were performed in UKMYC5 or UKMYC6 plates. Testing was carried out in 14 national and international laboratories. This method was validated by Rancoita *et al*, and performed as described [147]. Results were manually read and images were taken for additional automated assessment and quality control by AMyGDA software [144]. When results between laboratory visual assessment and AMyGDA did not correlate, plates were flagged as low quality and a third, independent assessment was performed by Citizen Science Project (BashTheBug.org). When two or three assessments did not correlate the Mtb isolate was removed from this dataset.

3.2.4.4 Core genome multi locus sequence typing

A core genome multi locus sequence typing was used to calculate the minimum spanning tree of serial patient isolates (Results 4.1). This was accomplished using SeqSphere v5.9 (Ridom, Münster, Germany) software, as described in Kohl *et al*. [148].

3.2.4.5 Mutation catalogue literature search

A thorough literature search was performed to summarize all BDQ/CFZ resistance-associated mutations in genes *Rv0678*, *atpE*, *pepQ*, and *Rv1979c*. Search engines used were: Google, Google Scholar, and PubMed, and included literature published from 2014 to June 2021. Key words used in literature search included: “Tuberculosis”, “TB”, “MTB”, “Mycobacterium tuberculosis”, “bedaquiline”, “BDQ”, “clofazimine”, “CFZ”, “treatment”, “drug resistance”, “patient”, “clinical report”, “MDR-TB”, “diarylquinolone”.

4. Results

4.1 Multi-drug and extensively drug resistant intra-patient resistance evolution of a single *Mycobacterium tuberculosis* complex strain

MDR/XDR-TB infections are especially hard to treat and require long-lasting, combination therapies (nine months or longer) [96]. Therefore, elucidating long-term microbial adaptations in the course of the therapy is particularly important. Through analysis of MDR-TB patient-derived sequential isolates, we can better understand how resistant populations emerge and trace successful/failed treatment interventions.

In this section, serial Mtb isolates were investigated from a patient who suffered from five distinct treatment episodes, and underwent a total of 27 years of anti-TB treatment. Thirteen isolates were recovered from the final TB episode and analyzed by WGS to determine newly emerging mutations under the therapy. The molecular data was coupled with results from phenotypic DST and the analysis of an extensive patient treatment history. This study described the emergence of seven additional drug resistances while under therapy, observed several heteroresistant populations, and correlated treatment failures with treatment regimens at a given time point.

4.1.1 Patient History

A native-born German patient was first diagnosed with pulmonary TB in Western Germany at the age of four, and treated over four months with isoniazid (INH), para-aminosalicylic acid (PAS), and a streptomycin (SM) derivative (dihydrothenat). Although the treatment was classified as successful, the patient suffered an additional four relapse or reinfection events, which included 4 months, 41 months, 88 months and finally 216 months of treatment (Appendix B, Table B.1). In the patient records, an instance of treatment non-compliance was noted, as was immunosuppressive behavior such as smoking cigarettes and alcohol abuse. It was not mentioned that the patient suffered from immunocompromising disorders/diseases (such as human immunodeficiency virus). Although previous therapy interventions were successful, the patient succumbed to infection in the final treatment period.

The treatment regimen of this patient was frequently changed, especially throughout the final infectious episode. Drug regimens were not always consistent with phenotypic DST, resulting in regimens consisting of only two, one, or even no effective drugs in the final 18 years of treatment (Figure 4.1.1).

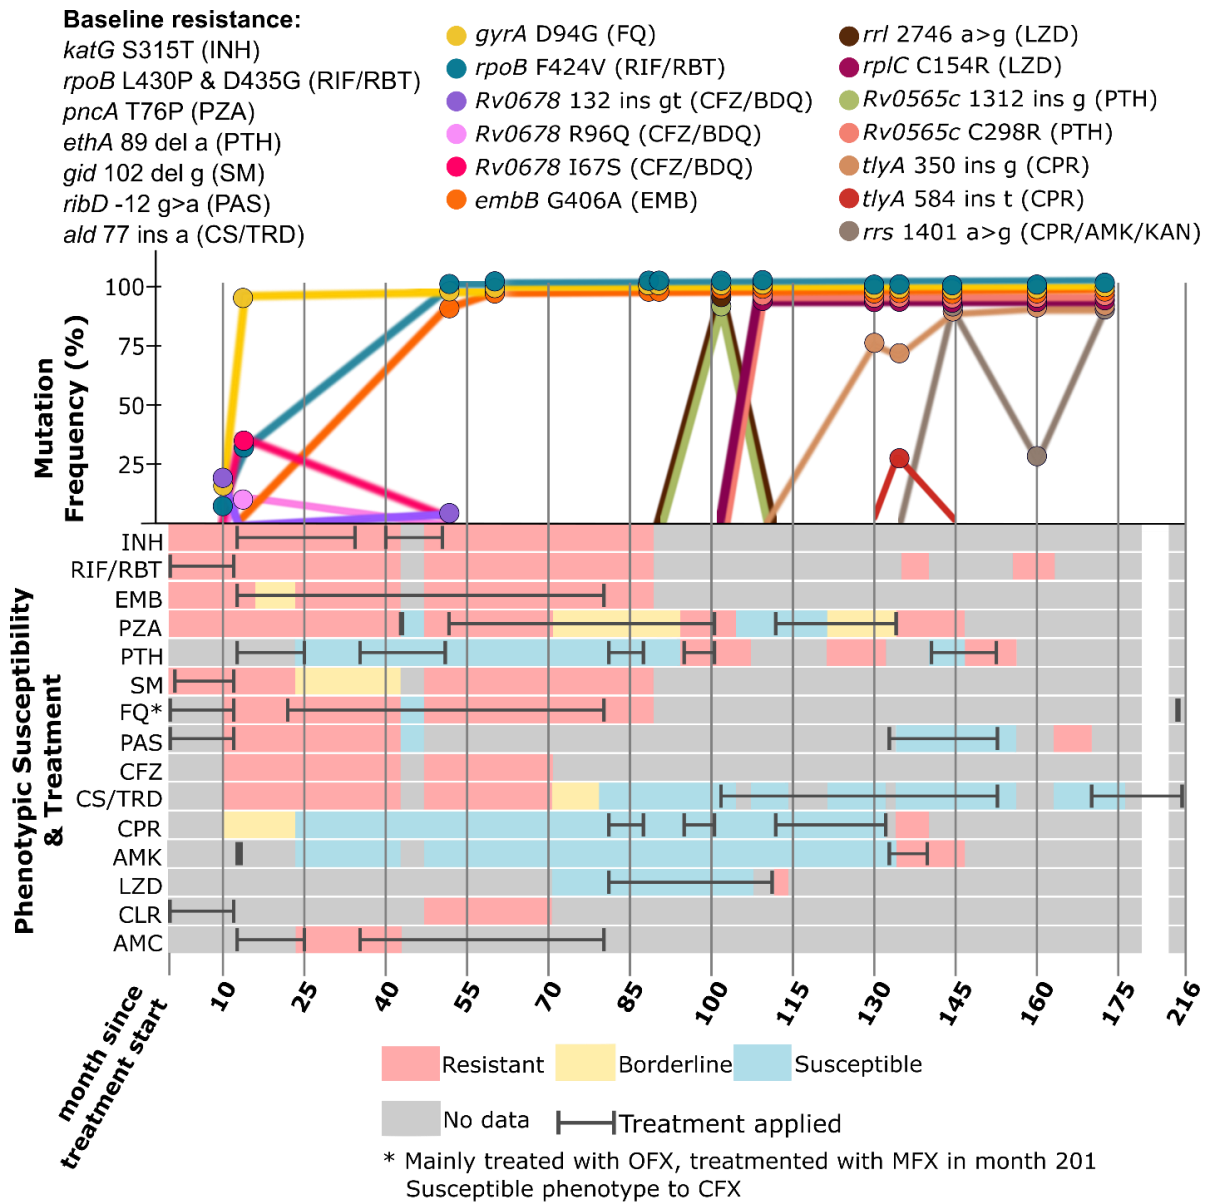

Figure 4.1.1: Final treatment episode: treatment history, phenotypic drug susceptibility results, and genetic diversity of resistance-associated mutations. Whole genome sequencing data is presented in the upper panel, and describes mutation frequency (y-axis) of emerging resistance mutations. Circles in the upper panel indicate when bacterial isolates were acquired from the patient. The lower panel shows results from phenotypic drug susceptibility testing as either resistant (red), borderline (yellow), susceptible (blue), or no data (gray). Dark gray bars which overlap phenotypic susceptibility testing, indicate when each drug was included in treatment. Adapted from Sonnenkalb *et al.* 2021 [87]

AMK: amikacin, AMC: amoxicillin+clavulanic acid, BDQ: bedaquiline, CFX: ciprofloxacin, CFZ: clofazimine, CLR: clarithromycin, CPR: capreomycin, CS: cycloserine, EMB: ethambutol, FQ: fluoroquinolone, INH: isoniazid, KAN: kanamycin, LZD: linezolid, MFX: moxifloxacin, OFX: ofloxacin, PAS: para-aminosalicylic acid, PTH: prothionamide, PZA: pyrazinamide, RIF: rifampicin, RBT: rifabutin, SM: streptomycin, TRD: terizidone

4.1.2 Intra-patient microevolution towards extensively drug resistant tuberculosis

Thirteen serial isolates which were collected throughout the final infectious episode (over 13 years), were analyzed via WGS, to predict drug resistance/susceptibility based on Research Center Borstel's mutation catalogue [146], [149]. Core genome multilocus sequence typing on these isolates confirmed clonal evolution of a single strain with a maximum distance of four or less alleles between sequential isolates, excluding a re-infection event (Figure 4.1.2).

Ten months after treatment began, the first bacterial isolate was obtainable for WGS. This isolate revealed baseline resistance to seven different antibiotics due to the following mutations: *katG* S315T for INH, *rpoB* L430P and D435G for rifampicin/rifabutin (RIF/RBT), *pncA* T76P for pyrazinamide (PZA), *ribD* at -12 g>a for PAS, *ethA* 89 del a for prothionamide (PTH), *gidB* 102 del g for SM, *ald* 77 ins a for cycloserine/terizidone (CS/TRD) which confirmed phenotypic DST results (Figure 4.1.1). INH, RIF, PZA, SM, PAS, PTH, TRD, ethambutol (EMB), capreomycin (CPR), and clarithromycin (CLR) were all included in previous treatment regimens for at least three consecutive months, but most were prescribed for ten or more months (Appendix B, Table B.1).

In month 13, phenotypic resistance was found to FQ drugs, mediated by the mutation *gyrA* D94G (Figure 4.1.1). This resistance arose after one year of ofloxacin (OFX) treatment (Appendix B, Table B.1). The subsequent isolate was collected nearly three years later (month 47), and revealed genotypic resistance to EMB mediated by *embB* G406A. Phenotypic resistance had already been detected in month 22, yet EMB was included in the treatment regimen from month 13 to 81. A third RIF/RBT associated mutation (*rpoB* F424V) was co-selected with *embB* G406A, and likely arose during the first 12 months of treatment (when RBT was prescribed) (Figure 4.1.1).

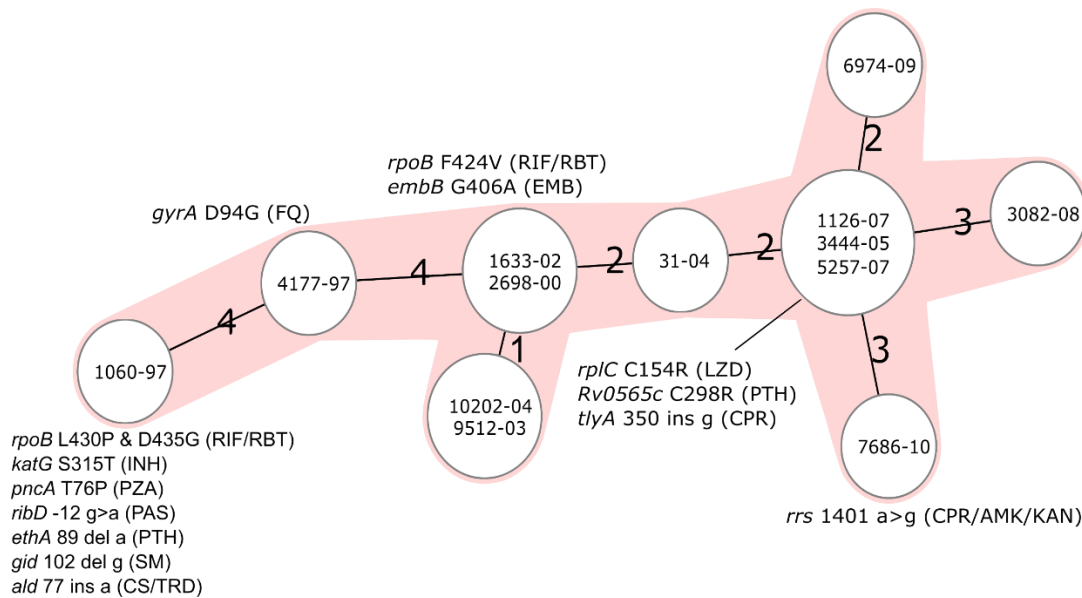

Figure 4.1.2: Minimum spanning tree based on a core genome multi locus sequence type analysis of thirteen serial isolates. Thirteen patient-derived serial isolates were whole genome sequenced and analyzed by core genome multi locus sequence typing. Number on connecting lines between nodes designates allele differences between isolates. Resistance-associated mutations (and linked drug) indicated next to isolate in which it was first fixed in the genome. Adapted from Sonnenkalb *et al.* 2021 [87].

AMK: amikacin, AMC: amoxicillin+clavulanic acid, BDQ: bedaquiline, CFZ: clofazimine, CLR: clarithromycin, CPR: capreomycin, CS: cycloserine, EMB: ethambutol, FQ: fluoroquinolone, INH: isoniazid, KAN: kanamycin, LZD: linezolid, MFX: moxifloxacin, PAS: para-aminosalicylic acid, PTH: prothionamide, RIF: rifampicin, RBT: rifabutin, SM: streptomycin, TRD: terizidone, PZA: pyrazinamide

The isolate taken in month 108, following 26 months of LZD therapy, harboured the mutation *rpIC* C154R at 100% frequency mediating LZD resistance. The mutation *Rv0565c* C298R, was co-selected with the LZD-linked mutation, and was likely responsible for the PTH resistance phenotype detected. These mutations emerged incredibly fast, in the four months since the previous isolate was collected. Next, CPR resistance was genotypically predicted in month 130, by the mutation *tlyA* 350 ins g (at a frequency over 75%). Finally, phenotypic and genotypic resistance to all second line injectables (CPR plus AMK and KAN) was attributed to the mutation *rrs* 1401 a>g detected in month 145. In total, resistance arose to seven anti-TB drugs mediated by five high-confidence resistance-associated mutations, over 13 years of MDR/XDR-TB treatment.

4.1.3 Evolutionary arms race of individual subpopulations

To understand resistance development more precisely, the presence of hetero-resistance (gWT and mutant alleles or several mutant alleles in a single population) populations was investigated, plus the emergence and extinction of resistant subpopulations over the course of the therapy. This was accomplished by analyzing mutations in genes implicated in resistance and compensatory evolution at a population frequency of >1% (Appendix B, Table B.2). All variants detected at a frequency below 75%, were statistically validated using binoSNP (Appendix B, Table B.3), a software developed for calling and verifying low-frequency SNPs from short-read Illumina® sequencing data [92]. In total, ten low-frequency resistance mediating mutations were observed, which fluctuated in the bacterial population before they reached fixation and/or disappeared in subsequent isolates (Appendix B, Table B.2; Figure 4.1.1).

As mentioned in the previous section, FQ resistance was attributed to *gyrA* D94G and became fixed at month 13. This mutation was already identified in the preceding isolate, three months prior, at a frequency of 21%. At month 10, a third RIF/RBT associated mutation, *rpoB* F424V, was detected at a frequency of 5%, then 30% in the subsequent isolate, followed by 96% then 100% in the two following isolates (Appendix B, Table B.2). Both of these mutations arose while under OFX (FQ) and RBT treatment.

Early isolates collected in months 10 and 13, but also month 47, harboured fluctuating BDQ/CFZ associated *Rv0678* mutations (Figure 4.1.1, Appendix B, Table B.2). First, the mutation *Rv0678* 132 ins gt was identified at 22% in the month 10 isolate, but was not observed in the subsequent isolate, then again appeared at only 3.6% in month 47 before it disappeared from the population. Similarly, in month 13, a heterogeneous population of *Rv0678* I67S (37%) and R96Q (10%) was detected, however, these two mutations were not found in any other isolate. Interestingly, these mutations arose and fluctuated without exposure to BDQ or CFZ, their resistance-associated drugs. However, phenotypic CFZ DST was conducted at that time and indicated resistance, likely attributed to these mutations.

Another heteroresistance event was observed, relating to CPR (Figure 4.1.1; Appendix B, Table B.2). In month 130, *tlyA* 350 ins g was first detected at a frequency of 79%. In the subsequent isolate (month 135), this mutation decreased to 71% coinciding with the appearance of *tlyA* 584 ins t at 28%. The next isolate, collected in month 144, revealed the fixation of *tlyA* 350 ins g and the loss of 584 ins t.

Finally, in later isolates, the resistance mutation *rrs* 1401 a>g was found fixed in the population at 100%. This mutation is responsible for second-line injectable drug (CPR, AMK, and KAN) cross-resistance, and

arose following 20 months of CPR then 7 months AMK treatment (Figure 4.1.1, Appendix B, Table B.2). Surprisingly, this mutation decreased to a 30% frequency in the preceding isolate. About one year later, *rrs* 1401 a>g was again fixed in the population at 99% frequency, absent treatment with any associated drugs.

4.1.4 Compensatory and tolerance associated mutations selected during treatment

Finally, three mutations linked to bacterial fitness and drug tolerance were selected in the last available isolates. The mutation F334L in the gene *prpR* (*Rv1129c*) linked to drug tolerance [150], was first found in month 92, was not observed in month 104 isolate, but was then fixed in the population at month 108 (Appendix B, Table B.2).

Another two mutations arose in the monooxygenase *Rv0565c*, a gene with a possible compensatory mechanism which is discussed to overcome fitness defects brought on by mutations in the monooxygenase *ethA* gene (activating the drugs ethionamide (ETH) and PTH) (Appendix B, Table B.2)[151]. These mutations in *Rv0565c* developed in isolates after the mutation *ethA* 89 del a. First, the mutation *Rv0565c* 1312 ins g arose to 97% frequency in month 104, but was lost in all proceeding isolates. In the subsequent isolate, a second mutation *Rv0565c* C298R was detected at 99% and remained fixed in the population.

4.2 An experimental model of antibiotic resistance evolution in bacteria of the *Mycobacterium tuberculosis* complex

As seen in the previously described treatment case, drug selection pressure especially in sub-optimal treatment regimens is shaping the evolutionary trajectories of bacterial populations. Still, conditions for selection of resistant subpopulations have not been fully explored for Mtb strains, and the MSW, meaning the drug concentration range in which resistant subpopulations can be selected, has not been well defined. As several studies have shown that a variety of pathological niches within patients exist in which not all drugs can penetrate at a therapeutic level [111]–[114], [152]–[155], it is crucial to understand the evolutionary impact of low-concentration drug exposure on resistance development of Mtb bacterium.

To address this question, a work-flow was designed for a sub-MIC evolution model performed *in vitro*, which included long- and short-term antibiotic exposure of the Mtb reference strain H37Rv (ATCC 27294) (Figure 4.2.1). Each evolutionary experiment was conducted over five bacterial culture passages, allowing for analysis of over 17 bacterial generations (Appendix C, Table C.1). Throughout the passaging process, bacterial quantification was performed by CFU plating and OD measurements. In addition to normal CFU plating, bacteria were plated on solid media supplemented with antibiotics at concentrations 1- to 5-fold higher than the MIC to the given drug. The proportion of mutants which arose in the total population over time was quantified (mutants/million CFU). Finally, single colonies were picked and re-cultured from selection plates to characterize the genotype and phenotype of single mutants and performed deep sequencing of total colony populations from a particular plate to investigate the overall diversity of resistance-associated variants (Figure 4.2.1). These experiments were carried out with important MDR-TB treatment drugs: MFX, BDQ, and CFZ.

Figure 4.2.1: Experimental flow chart. (1) Evolutionary experiments were conducted by exposing H37Rv to sub-minimum inhibitory concentrations (MIC) of antibiotics over 20 days, i.e. five culture passages. (2) Growth was measured at each culture passage as optical density (OD) and (3) quantified by colony forming unit (CFU) plating. (4) Mutant population was also quantified through CFU plating on solid agar plates supplemented with antibiotics at the strain MIC or higher. (5) Bacterial colonies which grew on antibiotic supplemented media were collected and whole genome sequencing was conducted for mutant population diversity evaluation. (6) Further, single colonies were isolated from selective agar plates and were (7) genotyped by whole genome sequencing and (8) phenotyped by drug susceptibility testing in resazurin microtiter plate assays, to evaluate the MIC.

4.2.1 Developing an evolution model for *Mycobacterium tuberculosis* adaptation to antibiotics

The initial parameters to be established for the sub-MIC evolution model were the appropriate drug concentrations to be included. First, the MIC of the H37Rv reference strain was ascertained by REMA. The MIC here for MFX was 0.12 mg/L, 0.25 mg/L for BDQ, and 0.5 mg/L for CFZ. Since the bacterial inoculum was higher in these evolutionary experiments (1×10^7 CFU/mL) than in REMA (1×10^5 CFU/mL), the MIC, 1:2, 1:4, 1:8, and 1:16 the MIC of each drug was determined for the higher inoculum. Two bacterial passages were carried out, and the four highest concentrations which had a final growth measurement of OD >0.1 were selected for the evolutionary experiments (Figure 4.2.2).

Figure 4.2.2: Sub-minimum inhibitory drug exposure of moxifloxacin, bedaquiline, and clofazimine over two culture passages. *Mycobacterium tuberculosis* complex strain H37Rv was cultured in 50 mL 7H9 medium and exposed to a range of antibiotic concentrations, starting at 0.12 mg/L for MFX, 0.25 mg/L for BDQ, and 0.5 mg/L for CFZ, and decreasing by 1:2 dilutions. Optical density of 600nm (OD) was measured at the end of each passage as an indication of bacterial growth. An OD below 0.1 (red line) was determined as insufficient growth.

Each experiment was conducted two times, and drug concentrations were tested in 1-fold dilutions (MIC, 1:2 MIC, 1:4 MIC, etc.). Of the MFX concentrations tested, 0.06, 0.03, 0.015, and 0.008 mg/L of MFX exposure did not inhibit the Mtb growth below an OD of 0.1 (Figure 4.2.2A). After two passages of 0.12 mg/L MFX exposure, the OD was 0.05, and therefore excluded from future experiments. For BDQ, all concentrations tested did not inhibit growth of the H37Rv strain below an OD of 0.1 (Figure 4.2.2B). Final evolutionary experiments with BDQ included 0.12, 0.06, 0.03, 0.015, and 0.008 mg/L. Finally, experiments with CFZ indicated a concentration of 0.5 mg/L CFZ inhibited growth with an OD <0.2, and all lower concentrations tested (0.25, 0.12, 0.06, 0.03, and 0.015 CFZ) grew to an OD >0.1 after two passages (Figure 4.2.2C). The concentrations included in the final CFZ experiment were 0.03, 0.06, 0.12, and 0.25 mg/L CFZ.

These experiments were carried out over five culture passages, with samples taken at the beginning (passage 1: day 4), middle (passage 3: day 12) and end (passage 5: day 20) of the experiment (Figure 4.2.3). On average, there were 3.4 ± 0.8 bacterial generations per passage, with a total of 17 generations per experiment (Appendix C, Table C.1). Evaluation of resistant populations and mutation characterization was accomplished by WGS and REMA MIC testing.

Figure 4.2.3: Sub-minimum inhibitory concentration evolution model experimental design for resistant variant selection, detection and analysis. (1) A pre-culture was started from frozen stocks of *Mycobacterium tuberculosis* complex strain H37Rv, (2) after recovery (5-7 days) some bacterial culture was transferred into new culture bottles and exposed to sub-minimum inhibitory concentrations (MIC) of antibiotics. (3) Bacteria were culture for 20 days including five bacterial passages, (4) cultures were sampled at passages 1, 3, and 5, (5) and grown on selective media plates, supplemented with the antibiotic. (6) After growth on selective media plates all colonies were pooled and deep sequencing was performed. (7) Single mutant colonies were isolated from selective media plates, characterized by whole genome sequencing and MIC tested by resazurin emission microtiter assays.

4.2.2 Sub-inhibitory antibiotic exposure selects and enriches drug resistant *Mycobacterium tuberculosis* complex bacterial populations

Three independent evolutionary experiments were conducted with MFX (Figure 4.2.4). Growth was initially evaluated by OD, which demonstrated a dose dependent growth inhibition as drug concentration exposure increased (Figure 4.2.4A). CFU analysis of the total bacterial population revealed that MFX exposure of 1:2 the MIC, or 0.06 mg/L MFX, reduced bacterial growth by an average of 9×10^7 CFU/mL, as compared to the growth of the unexposed (antibiotic free control) bacteria ($p=2.87 \times 10^{-4}$ _{passage1}, 0.024 _{passage3}, 2.7×10^{-6} _{passage5}) (Figure 4.2.4B; Appendix C, Table C.2). Exposure to 1:4 the MIC, or 0.03 mg/L MFX, significantly inhibited bacterial growth only after 5 passages ($p=2.9 \times 10^{-4}$), with a 2×10^7 CFU reduction. When exposed to MFX, 1:8 and 1:16 below the MIC, or 0.015 mg/L and 0.008mg/L MFX respectively, significant bacterial growth inhibition was not observed as compared to the unexposed (antibiotic free) culture.

Then, the number of mutants recovered overtime at the different experimental conditions was quantified by plating on selective plates (mutant per million CFU; Methods 3.2.1.2) (Figure 4.2.4C). Throughout the entire experiment, in the unexposed bacterial culture (antibiotic free control), an average of 0.03 mutants/million CFU was observed. After 4 days of antibiotic exposure (passage 1), the highest exposure concentration, 0.06 mg/L MFX, exhibited ten times more mutants (0.3 mutants/million CFU, $p=1.57 \times 10^{-9}$), as compared to the antibiotic-free control. Twelve days of antibiotic exposure (passage 3), resulted in a significant increase in recovered mutants at the two highest exposure concentrations, 0.03 and 0.06 mg/L MFX, with an average of 0.3 ($p=7.9 \times 10^{-5}$) and 67 mutants ($p=9.5 \times 10^{-7}$) per million CFU selected, respectively. Significantly more mutants were also selected after long-term (20 days) antibiotic exposure at concentration: 0.015 mg/L MFX as 0.1 mutants/million CFU selected ($p=2.4 \times 10^{-4}$), 0.03 mg/L MFX as 2 mutants/million CFU ($p=1.7 \times 10^{-7}$), and 0.06 mg/L MFX as 5.3×10^3 mutants/million ($p=9.5 \times 10^{-8}$). The lowest drug concentration, 1:16 below the MIC (0.008 mg/L MFX), displayed no significant increase in mutants compared to the unexposed bacteria throughout the experiment, with only 0.03 mutants/million CFU recovered (Figure 4.2.4C, Appendix C, Table C.2).

Figure 4.2.4: Sub-inhibitory exposure of moxifloxacin affects bacterial growth and mutant enrichment in a dose-dependent manner. The Mtbc lab strain H37Rv was exposed to four concentrations of moxifloxacin (MFX), 0.06, 0.03, 0.015, and 0.008 mg/L plus an antibiotic free control (0 mg/L MFX), with the highest concentration at 1:2 the minimum inhibitory concentration (MIC), MIC= 0.12 mg/L MFX. The bacteria were exposed to the antibiotic for 20 days, consisting of 5 culture passages. Bacterial samples were evaluated at three time points during the experiment, after day 4 or “passage: 1”, day 12 “passage: 3”, and day 20 “passage: 5”. (A) Optical density (OD) was measured at each time point and indicated bacterial growth. (B) As a second measure of bacterial growth and further quantification, colony forming units (CFU) were measured by plating each culture on 7H10 agar plates and after 14-21 days of growth, CFU were counted. (C) The cultures were also plated on 7H10 agar plates supplemented with the critical concentration of MFX (0.25 mg/L), and after 14 – 21 days of growth, CFU were counted. The number of counted mutant CFU was divided by the total CFU to get the mutant enrichment ratio, then multiplied by 10^6 to get mutants/million CFU.

Statistics: Three independent experiments were conducted, OD standard deviation was calculated from 3 independent experiments with one biological replicate each, too few values for statistical analysis. Bacterial growth: CFU and mutants/million CFU, were calculated from 3 independent experiments, one biological replicate each, and 3 to 5 technical replicates per biological replicate (9 to 15 values). Statistics was calculated as nonparametric multiple contrast test (Kruskal) with a confidence interval of 95%, p-values between drug exposed and the antibiotic free control (0 mg/L MFX): * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

The effect of sub-MIC drug exposure was similarly explored for BDQ (Figure 4.2.5). Bacterial growth as measured by OD, indicated a dose dependent decrease in growth as drug exposure concentration increased (Figure 4.2.5A). This dose-dependent decrease in growth was similarly observed by CFU analysis. The antibiotic free bacteria grew to 1.5×10^8 CFU/mL at each passage. The highest exposure concentration, 1:2 the MIC or 0.06 mg/L BDQ, reduced the bacterial growth by $2-5 \times 10^7$ CFU/mL, significantly more than the antibiotic free control at all passages ($p=3.4 \times 10^{-5}$ passage1, 4.9×10^{-3} passage3, 2.4×10^{-7} passage5) (Figure 4.2.5B, Appendix C, Table C.2). Exposure to 1:4 the MIC, or 0.03 mg/L BDQ, significantly reduced growth after passages 3 ($p=0.029$) and passage 5 ($p=2.8 \times 10^{-4}$) compared to the antibiotic free control, with a CFU reduction at $5 - 20 \times 10^6$ CFU/mL respectively. The concentration 0.015 mg/L BDQ, or 1:8 the MIC, inhibited growth from $8-32 \times 10^6$ CFU/mL compared to the control, which was significant after the 1st ($p=0.046$) and 5th ($p=9.8 \times 10^{-3}$) passages. The lowest concentration examined, 0.008 mg/L BDQ, 1:16 the MIC, did not show any significant growth defect as compared to the antibiotic free control, after all time points ($p > 0.05$).

Figure 4.2.5: Sub-inhibitory exposure of bedaquiline affects bacterial growth and mutant enrichment in a dose-dependent manner. The *Mycobacterium tuberculosis* complex lab strain H37Rv was exposed to four concentrations of bedaquiline (BDQ) (0.06, 0.03, 0.015, and 0.008 mg/L) plus an antibiotic free control (0 mg/L BDQ), with the highest concentration at 1:2 the minimum inhibitory concentration (MIC), MIC= 0.12 mg/L BDQ. The bacteria were exposed to the antibiotic for 20 days, consisting of 5 culture passages. Bacterial samples were evaluated at three time points during the experiment, after day 4 or “passage: 1”, day 12 “passage: 3”, and day 20 “passage: 5”. (A) Optical density (OD) was measured at each time point and indicated bacterial growth. (B) As a second measure of bacterial growth and further quantification, colony forming units (CFU) were measured by plating each culture on 7H11 agar plates and after 14-21 days of growth, CFU were counted. (C) The cultures were also plated on 7H11 agar plates supplemented with the MIC of BDQ (0.12 mg/L BDQ), and after 14 – 21 days of growth, CFUs were counted. The number of counted mutant CFU was divided by the total CFU to get the mutant enrichment ratio, then multiplied by 10^6 for mutants/million CFU.

Statistics: Three independent experiments were conducted, OD standard deviation was calculated from 3 independent experiments with one biological replicate each, too few values for statistical analysis. Bacterial growth: CFU and mutants/million CFU, were calculated from three independent experiments, with one biological replicate each, and three to five technical replicates per biological replicate (9 to 15 values). Statistics was calculated as nonparametric multiple contrast test (Kruskal) with a confidence interval of 95%, p-values between drug exposed and the antibiotic free control (0 mg/L BDQ): * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

The mutants recovered after each passage, increased over time with the most mutants observed at higher exposure concentrations (Figure 4.2.5C). The number of mutants recovered in the antibiotic-free control culture was 2.5 mutants/million CFU throughout the experiment. The highest exposure concentration, 1:2 the MIC or 0.06 mg/L BDQ, showed the uppermost mutant recovery as 21 mutants/million CFU after passage 1, 306 mutants/million CFU after passage 3, and 1×10^4 after passage 5, significantly more than the antibiotic free control ($p = 7.3 \times 10^{-5}$ passage 1, $p = 1.04 \times 10^{-6}$ passage 3, $p = 1.4 \times 10^{-13}$ passage 5) (Appendix C, Table C.2). The second highest exposure concentration, 1:4 the MIC or 0.03 mg/L BDQ, presented a significant mutant increase as compared to the antibiotic free control after passage 5 with an average of 119 mutants/million recovered ($p = 6.4 \times 10^{-14}$). Nevertheless, at a concentration exposure of 1:8 the MIC, 0.015 mg/L BDQ, a small but steady increase overtime was observed, from 6 mutants/million CFU after passage 3, to 8 mutants after passage 5, a significant increase as compared to the antibiotic free control at $p = 0.018$ and $p = 2.8 \times 10^{-10}$ respectively. There was no significant or observable increase in mutant population after exposure to 1:16 the MIC, 0.008 mg/L BDQ, as compared to the antibiotic free control.

These evolutionary experiments were the performed with CFZ (Figure 4.2.6). OD measurements indicated a reduction in growth, as CFZ exposure concentration increased (Figure 4.2.6A). After passage three (12 days), the highest exposure concentration 0.25 mg/L CFZ was no longer passaged due to high growth inhibition.

Figure 4.2.6: Sub-inhibitory exposure of clofazimine affects bacterial growth and mutant enrichment in a dose-dependent manner. The *Mycobacterium tuberculosis* complex lab strain H37Rv was exposed to four concentrations of clofazimine (CFZ) (0.25, 0.12, 0.06, and 0.03 mg/L) plus an antibiotic free control (0 mg/L CFZ), with the highest concentration at 1:2 the minimum inhibitory concentration (MIC), MIC= 0.5 mg/L CFZ. The bacteria were exposed to the antibiotic for 20 days, consisting of 5 culture passages. Bacterial samples were evaluated at three time points during the experiment, after day 4 or “passage: 1”, day 12 “passage: 3”, and day 20 “passage: 5”. (A) Optical density (OD) was measured at each time point and indicated bacterial growth. (B) As a second measure of bacterial growth and further quantification, colony forming units (CFU) were measured by plating each culture on 7H10 agar plates and after 14-21 days of growth, CFU were counted. (C) The cultures were also plated on 7H11 agar plates supplemented with the MIC of CFZ (0.5 mg/L CFZ), and after 14 – 21 days of growth, CFU were counted. The number of counted mutant CFU was divided by the total CFU to get the mutant enrichment ratio, then multiplied by 10^6 to get mutants/million CFU.

Statistics: Three independent experiments were conducted, OD standard deviation was calculated from 3 independent experiments with one biological replicate each, too few values for statistical analysis. Bacterial growth: CFU and mutants/million CFU, were calculated from three independent experiments, with one biological replicate each, and three to five technical replicates per biological replicate (9 to 15 values). Statistics was calculated as nonparametric multiple contrast test (Kruskal) with a confidence interval of 95%, p-values between drug exposed and the antibiotic free control (0 mg/L CFZ): * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

Although there was a slight downward trend in growth as drug exposure concentration increased, CFU analysis indicated no growth defect, except at the highest drug exposure concentration. Exposure to 0.25 mg/L CFZ or 1:2 the MIC, reduced bacterial growth as compared to the antibiotic free control by 9.4×10^7 CFU/mL after passage 1 ($p = 7.5 \times 10^{-4}$), and 1.4×10^8 CFU/mL after passage 3 ($p = 4.9 \times 10^{-4}$) (Figure 4.2.6B, Appendix C, Table C.2).

Even though the changes in drug concentration had little effect on growth, an overall dose dependent increase in mutant enrichment was observed (Figure 4.2.6C, Appendix C, Table C.2). The lowest exposure concentration, 1:16 the MIC or 0.03 mg/L CFZ, did not inhibit bacterial growth as compared to the antibiotic free control. After passage 1, all other exposure concentrations appeared to have a slightly higher mutant enrichment than the unexposed bacteria, which was significant at concentrations 1:2 the MIC (0.25 mg/L CFZ, $p = 1.1 \times 10^{-3}$) and 1:8 the MIC (0.06 mg/L CFZ, $p = 5.5 \times 10^{-3}$). After passage 3, the mutant population increased compared to the antibiotic free control at 3 mutants/million CFU to 7 mutants/million CFU after 0.06 mg/L CFZ exposure ($p = 1.9 \times 10^{-3}$), 34 after 0.12 mg/L CFZ exposure ($p = 0.016$), and 199 after 0.25 mg/L CFZ ($p = 2.2 \times 10^{-5}$). Finally, 20 days of antibiotic exposure (passage 5) an increase at 26 mutants/ million CFU after 0.06 mg/L CFZ exposure ($p = 2.4 \times 10^{-3}$) and 458 mutants/ million after 0.12 mg/L CFZ exposure ($p = 3.5 \times 10^{-5}$) was realized.

4.2.3 Cross-resistance selection of bedaquiline mutants after clofazimine exposure

Cross-resistance has been observed between CFZ and BDQ, when off-target mutations arise in the *Rv0678* gene, which regulates the expression of the *mmpS5-mmpL5* efflux system [76]. Therefore, it was questioned at what rate CFZ exposure selected for mutants which are also resistant to BDQ. To answer this question, evolutionary experiments were again performed by sub-inhibitory drug exposure with CFZ or BDQ, then the bacteria was plated on selective agar supplemented with BDQ (Figure 4.2.7). CFZ exposed cultures were plated from frozen back-up stocks.

Figure 4.2.7: Experimental flow chart: bedaquiline/clofazimine cross-resistance. (A) Evolutionary experiments were conducted by exposing the *Mycobacterium tuberculosis* complex strain H37Rv to low levels of antibiotics over a long period of time. (B) First the bacteria were exposed to sub-inhibitory concentrations of bedaquiline (BDQ) or clofazimine (CFZ). The cultures were then plated on BDQ selective media, and mutant enrichment was then compared between CFZ and BDQ, at correlating reductions in minimum inhibitory concentration values.

At passage 1, it was observed that the mutant enrichment following BDQ exposure was significantly higher compared to that of CFZ exposure at most concentrations: 1:16 MIC ($p=0.002$), 1:8 MIC ($p=0.01$), and 1:2 MIC ($p=8.85 \times 10^{-2}$) (Figure 4.2.8; Appendix C, Table C.3). However, in all subsequent passages, this effect decreased. After the 3rd passage, mutant enrichment was similar between both drugs, except at 1:8 below the MIC, in which 6 mutants over 2 mutants/million CFU were recovered after BDQ exposure than CFZ exposure ($p=0.042$). There was not a difference in mutant enrichment between BDQ and CFZ exposure after passage 5. The 1:2 MIC exposure concentration of CFZ was excluded at passage 5, since passaging was discontinued after the 3rd passage.

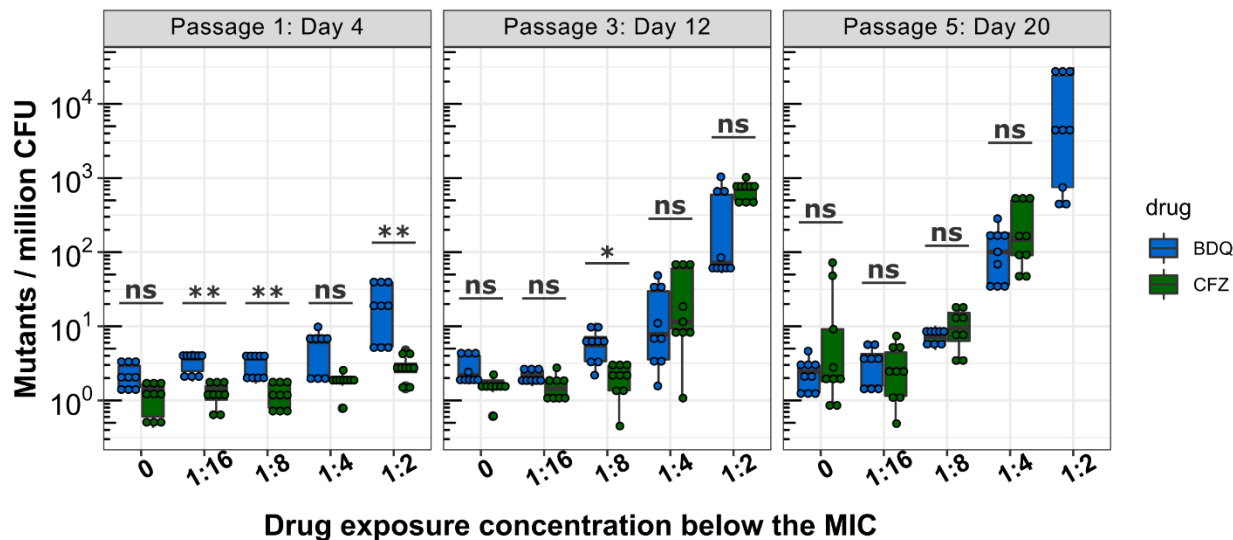

Figure 4.2.8: Cross-resistance comparison of bedaquiline and clofazimine exposure. The *Mycobacterium tuberculosis* complex lab strain H37Rv was exposed to four concentrations below the minimum inhibitory concentration (MIC) of bedaquiline (BDQ; blue) or clofazimine (CFZ; green). BDQ exposure concentrations were 0.06 mg/L (1:2 MIC), 0.03 mg/L (1:4 MIC), 0.015 mg/L (1:8 MIC), 0.008 mg/L (1:16 MIC), or no antibiotic (0). CFZ concentrations used were 0.25 mg/L (1:2 MIC), 0.12 mg/L (1:4 MIC), 0.06 mg/L (1:8 MIC), 0.03 mg/L (1:16 MIC), no antibiotic (0). The bacteria were exposed to the antibiotic for 5 culture passages. Bacterial samples were evaluated after passage 1 (4 days), passage 3 (12 days), and passage 5 (20 days). At each time point, the cultures were plated on 7H11 agar plates containing the critical concentration of BDQ (0.12 mg/L), and after 14 – 21 days of growth on plates, colony forming units (CFU) were counted. The number of counted mutant CFU was divided by total CFU for the mutant enrichment ratio, then multiplied by 10⁶ to get mutants/million CFU.

Statistics: Three independent experiments were conducted, mutants/million CFU were calculated with one biological replicate per experiment, and three to five technical replicates per biological replicate (9 to 15 values). Statistics were calculated as a pairwise comparison of CFZ and BDQ by nonparametric multiple contrast test (Kruskal) with a confidence interval of 95%. *p<0.05, **p<0.01, ***p<0.001.

Overall, it was observed that after short term drug exposure, BDQ has a higher capacity to enrich BDQ resistant mutants than does CFZ. However, after long-term exposure, BDQ and CFZ have nearly equal capacities to enrich BDQ mutant populations.

4.2.4 Sub-inhibitory drug exposure selects a diversity of mutations in resistance-associated genes

The experiments performed so far with sub-MIC *in vitro* evolution under MFX, BDQ, and CFZ exposure revealed that sub-inhibitory drug exposure (up to 1:8 below the MIC) selected and enriched drug resistant populations (Results 4.2.2). It was then questioned whether these mutant populations were composed of a diversity of variants, or whether only few, or just one variant was selected. Therefore, WGS was conducted on the total mutant population of a given selection plate, grouped by drug exposure concentration and isolation time point (passage) (Figure 4.2.1). Further, single mutant colonies were isolated, which were then sub-cultured for characterization of resistance phenotype (MIC by REMA) and genotype (WGS) (Figure 4.2.1).

Moxifloxacin

Three independent experiments were conducted with MFX, as previously described (Figure 4.2.3). A total of 45 bacterial populations were evaluated, grouped by experiment, exposure concentration, and time point (passage). Of DNA isolated from 45 bacterial populations, 41 were successfully sequenced and analyzed (four were excluded due to low quality DNA isolation or sequencing). WGS deep sequencing of DNA was performed on the Illumina® platform, with a base coverage depth ranging from 277-1087x and an average of 595x (Appendix C, Table C.4).

It is known that resistance to MFX and other FQ drugs arise due to SNPs mainly in the quinolone resistance determining region (QRDR) of the *gyrA* (codon 74 to 113) and *gyrB* (codon 461 and 504) genes [156], [157]. Here, all high and low-frequency variants detected throughout the *gyrA* and *gyrB* genes were determined, and variant positions were excluded which did not have at least one read in both forward and reverse orientation, and a frequency >1%. Through population sequencing, 14 different SNPs were detected, seven in *gyrA* and seven in *gyrB* (Table 4.2.1). The most common mutations detected in different populations were *gyrA* A90V, *gyrA* D94G, and *gyrB* N499D; which appeared in 38, 25, and 23 different populations respectively. The least common variants detected were *gyrA* D94H, *gyrB* N499I, and *gyrB* N499T, each of which only appeared in one population.

Table 4.2.1: Summary of variant diversity in *gyrA* and *gyrB* genes of mutant population after moxifloxacin evolutionary experiments. DNA from mutant populations was individually collected and pooled by experiment, time point, and drug exposure concentration. “Appearance in n-populations” indicates the number of independent populations in which the variant was detected.

Gene	Gene name	Variant position	Variant	Type	Reference allele	Alternative allele	Appearance in n-populations
<i>Rv0005</i>	<i>gyrB</i>	6101	E288_	SNP	g	t	2
<i>Rv0005</i>	<i>gyrB</i>	6117	W293S	SNP	g	c	5

N - number, SNP - single nucleotide polymorphism

Next, single mutant colonies were selected at random and sub-cultured for further phenotypic and genotypic analysis of the resistance-associated mutation (Figure 4.2.3). From two independent experiments, a total of 140/150 mutants were successfully characterized (10 were excluded due to low quality DNA isolation or sequencing) (Table 4.2.2).

Each mutant harbored one non-synonymous SNP in a resistance-associated gene, including three *gyrB* mutations and seven *gyrA* mutations (Table 4.2.2). The most abundant mutations were *gyrA* A90V and *gyrB* N499D which were independently selected 68 and 26 times respectively. The two least commonly selected mutations, each only selected one time, were *gyrB* N499K and E501D. All mutations presented an 8- to 33-fold MIC increase as compared to the gWT susceptible ancestor (Figure 4.2.9A). The lowest MIC observed was 0.5 mg/L MFX (8- to 16-fold higher than the gWT MIC) and the maximum MIC increase observed was at 2 mg/L MFX (16- to 33-fold higher than the gWT MIC) (Table 4.2.2).

Table 4.2.2: Genotypic and phenotypic characterization of resistant variants isolated after moxifloxacin exposure. Whole genome sequencing was conducted to detect the resistant variant under selection, minimum inhibitory concentration (MIC) was measured by resazurin emission microtiter assay and compared to the genetically wild-type (gWT) susceptible ancestor.

Gene name	Variant position	Variant	Ref. allele	Alt. allele	Number of isolates	Selection conc. (mg/L MFX)	MFX MIC (mg/L)	Fold MIC increase

<i>gyrA</i>	7582	D94G	a	g	24	0.5	1-2	8-33

Alt. - alternative, Ref. - reference, MFX - moxifloxacin

Next, all thirteen MFX (FQ) resistance-associated variants observed after population sequencing (Table 4.2.1) and single mutant selection (Table 4.2.2) were mapped on the sequences of the *gyrA* and *gyrB* genes (Figure 4.2.9B). Here, it was observed that over 87% of the variants appeared within the QRDR. Two of the thirteen detected variants were not observed in the QRDR (*gyrB* E288_ and W293S). Since these mutations were not independently selected and characterized, the phenotypic effect could not be determined (i.e. resistant or benign).

Figure 4.2.9: Characterization of mutations throughout *gyrA* and *gyrB* genes. (A) Single variants were isolated, minimum inhibitory concentration was determined and compared to the genetically wild-type (gWT) susceptible ancestor. (B) All mutations detected in population sequencing (Table 4.2.1.) and selected as single colonies (Table 4.2.2) were mapped along *gyrA* and *gyrB* genes, with an enhanced view of the quinolone resistance determining regions (QRDR).

Bedaquiline

As described above, exposure to sub-inhibitory concentrations of BDQ led to the selection of BDQ resistant clones on BDQ supplemented media (Figure 4.2.6). To determine the nature and diversity of mutations resulting in BDQ resistance, WGS was performed focusing on previously described BDQ resistance associated genes (Figure 4.2.3). Several mutations occurred in the genes *Rv0678* and *atpE*, which have been previously described as conferring low- and high-level BDQ resistance [76], [158]–[160]. No mutations were detected in other BDQ resistance related genes (i.e. *pepQ* and *Rv1979c*).

From three independent experiments, DNA from a total of 45 bacterial populations was isolated, 43 of which were successfully sequenced (two were excluded due to low quality DNA isolation). Each DNA sample was deep sequenced with a coverage depth from 205-383x, and an average of 284x (Appendix C, Table C.5). The threshold for calling a mutation was at least 1 forward and 1 reverse read, and a frequency >1%.

WGS of mutant populations revealed 39 unique SNPs possibly conferring BDQ resistance (Table 4.2.3). Of these resistances associated variants, 37 were located throughout the *Rv0678* gene including 11 indels and 28 non-synonymous SNPs (Appendix C, Table C.6). The most common *Rv0678* mutations were 193 del g, L43P, and A99V; which appeared in 34, 33, and 32 different populations respectively (Table 4.2.3). Also, two variants were detected in the *atpE* gene, A63P in three different populations, and D28G in one population (Table 4.2.3).

Table 4.2.3: Summary of variant diversity in *Rv0678* and *atpE* genes of mutant population after bedaquiline evolutionary experiment. DNA from mutant populations was individually collected and pooled by experiment, time point, and drug exposure concentration. “Appearance in n-population” indicates the number of independent populations in which the variant was detected. Extended table in Appendix C, Table C.6.

Del - deletion, Ins - insertion, SNP - single nucleotide polymorphism

The mutations found in clones derived from single colonies after BDQ exposure are described along with mutant clones recovered after CFZ exposure in the following section.

Clofazimine

Finally, the mutant population diversity of CFZ exposed bacteria was examined. In total, DNA from 45 populations was collected for analysis, of which 38 were successfully sequenced (7 were excluded due to low quality DNA isolation or sequencing). Deep sequencing of DNA was achieved with an average depth of 336x, ranging from 257-422x (Appendix C, Table C.7). In this dataset, mutations were detected in the CFZ resistance-associated genes *Rv0678* and *pepQ* (*Rv2535c*) but not in *Rv1979c*.

WGS revealed 73 possible resistance conferring mutations, with 60 variants throughout *Rv0678* and 13 in *pepQ* (Table 4.2.4). In *Rv0678*, there were 31 indels, 38 non-synonymous SNPs, and one synonymous SNP (Appendix C, Table C.8). Within the *pepQ* gene, there were 8 non-synonymous and 5 synonymous SNPs observed. The most frequently observed *Rv0678* variants were A99V, G121E, or R50W which were observed in 33, 25, and 22 different experimental populations (Table 4.2.4). Interestingly, A99V was also one of the most commonly selected variants after BDQ exposure (Table 4.2.3). Finally, the three variants which appeared most often in *pepQ* were A87G, L114R, and A90G and were detected 9, 4, and 2 times respectively.

Taken together, the diversity of mutations detected by deep sequencing, which possibly conferred BDQ and/or CFZ resistance, was quite extensive with 96 unique mutations throughout three genes, and 14 substitutions which arose after both BDQ and CFZ exposure (Appendix C, Tables C.6 & C.8).

Table 4.2.4: Summary of variant diversity in *Rv0678* and *pepQ* (*Rv2535c*) genes of mutant population after clofazimine evolutionary experiment. DNA from mutant populations was individually collected and pooled by experiment, time point, and drug exposure concentration. “Appearance in n-population” indicates the number of independent populations in which the variant was detected.

Extended table in Appendix C, Table C.8.

Bedaquiline & Clofazimine selected mutants

Single bacterial colonies were isolated from selective agar plates supplemented with 0.12 mg/L BDQ, 0.25 mg/L BDQ, or 0.5 mg/L CFZ. A total of 150 mutant colonies were isolated from two independent BDQ experiments, with a total of 128 colonies successfully genotyped (WGS) and 117 phenotypically characterized (i.e. MIC). From the CFZ exposure experiments, 97 colonies out of 120 were successfully sequenced and 102 phenotypically characterized.

Of the 215 mutant colonies analyzed, 68 different nucleotide substitutions were detected, including 45 amino acid changes (Appendix C, Table C.9). The mutants selected harbored resistance-associated variants in two genes, five in *atpE* (*Rv1305*) and 63 in *Rv0678*, interestingly thirteen isolated clones did not harbor a mutation in any resistance-associated genes (further described in Results 4.3). Nine identical mutations were independently selected after both BDQ and CFZ experiments (Table 4.2.5). The two most common mutations selected were 192 ins g and A99V, which were independently selected in 18 and 17 clones respectively.

Table 4.2.5: Genotypic and phenotypic characterization of resistant variants isolated after bedaquiline or clofazimine evolutionary experiments. Whole genome sequencing was conducted to detect the resistant variant under selection, minimum inhibitory concentration (MIC) was measured by resazurin emission microtiter assay and compared to the genetically wild-type (gWT) ancestor. Table includes variants which were selected at least three times. Extended table in Appendix C, Table C.9.

Gene	Variant position	Variant	Type	BDQ MIC (mg/L)	CFZ MIC (mg/L)	Number of isolates	BDQ or CFZ isolate	Selection conc. (mg/L)

Alt. - alternative, BDQ - bedaquiline, bp – base pairs, CFZ - clofazimine, conc. - concentration, Del - deletion, Ins - insertion, NA - not available, Ref. - reference, _ - stop codon insertion

When compared to the gWT susceptible ancestor, mutations in *Rv0678* resulted in a 2- to 16-fold MIC increase to BDQ, and either no increase or up to a 12-fold MIC increase to CFZ (Appendix C, Table C.9). Most clones which harbored an *atpE* mutation did not present an increase in MIC to CFZ, with exception to some clones which harbored an E61D or A63P mutation, and demonstrated a 4-fold MIC increase as compared to the gWT to CFZ. All *atpE* mutants demonstrated a substantial MIC increase to BDQ, from 4- to ≥ 20 -fold more than the gWT MIC (Table 4.2.5).

Several clones which were isolated after the first passage (from two independent experiments) underwent MIC verification through a second phenotypic testing method: MGIT (Table 4.2.6). Here, *Rv0678* mutations exhibited an increased BDQ MIC from the gWT of 0.25-0.5 mg/L to ≥ 2 mg/L, and CFZ MIC from 0.25 mg/L to 2 mg/L. Further, *atpE* mutations increased BDQ MICs above the highest tested concentration (MIC > 2 mg/L BDQ) and presented mild or no increase in CFZ MIC, as compared to the gWT.

Additional MIC testing conducted for DLM and LZD demonstrated no cross-resistance as the MIC was the same as the gWT for all mutant clones at ≤ 0.03 mg/L and ≤ 0.5 mg/L respectively. Although the gWT was not tested with LZD, the strains tested indicated an MIC below the WHO defined critical concentration of 1.0 mg/L.

To describe the diversity of mutations observed in all experiments performed, all resistance-associated mutations were mapped on the sequences of the *atpE*, *Rv0678*, and *pepQ* genes (Figure 4.2.10). This analysis allows for a visual representation of the mutational distribution throughout these resistance-associated genes, and the identification of potential hot-spot regions. In *atpE*, there were two areas where variants were clustered, around codon 28, and from codon 61 to 63. Mutations in the *Rv0678* gene were spread throughout the gene with no clear clustering regions. In the *pepQ* gene, there was one clustering region from codon 87 to 114. However, no mutants harboring a variant in *pepQ* were independently selected, so it is not clear these mutations lead to elevated BDQ or CFZ MICs.

Table 4.2.6: Mycobacterium growth indicator tube testing of *Rv0678* and *atpE* mutants. Drug resistant clones selected on bedaquiline agar plates (after passage one from two independent experiments) underwent minimum inhibitory concentration (MIC) testing by mycobacterium growth indicator tubes, performed by colleagues at the Super-National Reference Center for Mycobacteria, Borstel. Previous testing of the genetically wild-type (gWT) strain showed an MIC of 0.25-0.5 mg/L bedaquiline, 0.25 mg/L clofazimine, 0.015-0.03 mg/L for delamanid, and 1.0 mg/L for linezolid [96].

NA - not available, R - resistant, S - susceptible, _ - stop codon insertion

Figure 4.2.10: Mutations detected after *in vitro* experiments, mapped to *atpE*, *Rv0678*, and *pepQ* genes. Resistance-associated mutations detected after *in vitro* selection experiments in single isolated mutants and total mutant populations were designated along *Rv0678*, *atpE*, and *pepQ* genes at corresponding coding positions by non-synonymous single nucleotide polymorphisms, and by a protein disrupting mutation such as a stop codon insertion () or frameshift mutations - nucleotide insertion (ins) or deletions (del). Resistance-associated variants included from Appendix C, Tables C.6, C.8, and C.9.

4.2.5 Bedaquiline and clofazimine resistance-associated mutations described in patient cohorts

In the previous section, it was demonstrated that sub-MIC, long-term antibiotic exposure selected a diversity of resistance conferring mutations to BDQ and CFZ through mutations in *Rv0678*. Next, *in vitro* selected mutations were compared with mutations determined in a large patient-derived strain collection. This contributed to the development of a large variant catalogue, allowing genomic resistance prediction for BDQ/CFZ, and also gave a better view to the extent at which the sub-MIC evolution model reflects resistance evolution in Mtb strains obtained from patients.

In cooperation with the CRyPTIC consortium, a 14,151 clinical strain collection which included WGS and MIC data based on UKMYC5/6 microtiter broth plates was analyzed (Appendix C, Table C.10) [140], [147]. The whole dataset was filtered for strains with single mutations in *Rv0678*, *atpE*, *Rv1979c* or *pepQ*. Since *Rv1979c* and *pepQ* mediated resistance is not well described in patients, isolates with susceptible phenotypes were not included [161]–[163]. Altogether, 235 strains were found with a mutation in one of these four genes (Appendix C, Table C.10). Overall, 178 strains had mutations in *Rv0678*, three in *atpE*, 35 in *Rv1979c*, and 19 in *pepQ* (Table 4.2.7). Resistance profiles were determined on UKMYC5/6 plates and interpreted as >0.12 mg/L BDQ/CFZ as resistant, =0.12 mg/L BDQ/CFZ borderline, and <0.12 mg/L BDQ/CFZ susceptible.

Table 4.2.7 Patient cohort dataset summary. Of the 14,151 clinical isolates collected and characterized by Comprehensive Resistance Prediction for Tuberculosis: An International Consortium partners, 235 strains harbored a mutation in one of four bedaquiline (BDQ) / clofazimine (CFZ) resistance-associated genes; *Rv0678*, *atpE*, *Rv1979c*, or *pepQ*.

Implicated resistance-associated gene	Number of isolates	BDQ/CFZ resistant phenotype (>0.12 mg/L)	BDQ/CFZ borderline resistance (=0.12 mg/L)	BDQ/CFZ susceptible phenotype (<0.12 mg/L)	Strains with no CFZ MIC data
<i>Rv0678</i>	178	52 / 36	32 / 38	94 / 75	0 / 32
<i>atpE</i> (<i>Rv1305</i>)	3	3 / 1	0 / 1	0 / 1	0 / 0
<i>Rv1979c</i>	35	35 / 16	0 / 4	0 / 1	0 / 14
<i>pepQ</i> (<i>Rv2535c</i>)	19	19 / 2	0 / 3	0 / 3	0 / 11

In addition to this large CRyPTIC dataset, an in-depth literature search was included, in order to further define the genotypic landscape of BDQ (and CFZ) resistance conferring mutations (Appendix C, Table C.11). This study summarized all phenotypically resistant (based on study definition or WHO accepted critical concentration) patient-derived and *in vitro* isolates described in 28 studies. In total, 159 resistance conferring variants, 30 borderline, 26 benign/susceptible, and 15 with variable resistance profiles to BDQ were defined. For CFZ, these same strains presented 117 resistance-associated variants, 25 borderline, 23 benign/susceptible, and 15 with variable resistance/susceptibility (Appendix C, Table C.11).

To allow for an overview of the mutation diversity identified, all borderline and resistance-associated mutations found in strains obtained from patients throughout were mapped on the sequences of *Rv0678* (101), *atpE* (5), *pepQ* (5), and *Rv1979c* (5). Interestingly, an overlap of 13 mutations in the *in vitro* selected mutants and the patient-derived isolates was identified (Figure 4.2.11). Through gene mapping, it was possible to visually identify potential hotspot regions or “resistance determining regions” throughout the different genes. Mutations in *atpE* appeared to affect two regions at codons 28 and 61-63. Mutations in *Rv1979c* and *pepQ* are not so clearly clustered, therefore more variants are needed to determine potential hotspot regions. Finally, variants in *Rv0678* were diverse and appeared throughout the entire gene affecting 77 of 165 coding positions (Figure 4.2.11)

Since BDQ/CFZ resistance-conferring mutations appear throughout the *Rv0678* gene, it was attempted to locate hot-spot regions by evaluating the abundance of resistance conferring mutations by codon (Figure 4.2.14). This comparison included variants found in patient isolates including the CRyPTIC dataset and published literature, single selected *in vitro* clones from the sub-MIC evolution experiments, and *in vitro* population sequencing. In all three datasets, there were 10 codons which harbored a resistant conferring mutation, with six codons affected in patient-derived isolates and at least one of the *in vitro* datasets (Figure 4.2.12). When looking at the number of mutations over codon positions, it can be observed that the most highly affected codons are between codons 38 to 51, but also 61 and 68 (Figure 4.2.12).

Figure 4.2.12: Resistance association by codon position in Rv0678 gene. Overlapping mutations were compared between three datasets; *in vitro* population sequencing (Appendix C, Table C.6 & C.8), *in vitro* single selected mutants (Appendix C, Table C.9), and patient-derived isolates (Appendix C, Table C.11). Number of independent isolates detected throughout the datasets in each coding position; *in vitro* population sequencing noted as a single isolate. Adapted from Sonnenkalb *et al.* 2021 [140].

CRyPTIC - Comprehensive Resistance Prediction for Tuberculosis: An International Consortium

4.3 Defining evolutionary processes of a weak selection pressure on bacteria of the *Mycobacterium tuberculosis* complex – a quantitative analysis

In order to better understand the selection and enrichment of clonal subpopulations with particular mutations, especially in clonal competition in a heterogeneous population, several aspects related to the phenotype of the mutant harboring clones were addressed. First, the selection of off-target mutations, which were co-selected with a resistant variant was explored. Next, the MSW was determined and relative fitness of clones with different resistance mutations was investigated. Finally, a non-canonical resistance mechanism was uncovered using alternative WGS techniques.

4.3.1 Secondary mutations arise and are selected with resistant variants

As described in the previous sections, a set of clones with diverse resistance-associated variants were selected after the Mtbc H37Rv strain was exposed to sub-MICs of MFX, BDQ, or CFZ. All mutant clones harbored only one variant in a resistance-associated gene, accompanied with an elevated MIC as compared to the gWT ancestor. Previous studies have shown that additional mutations can arise after (and in some cases before) a resistance-associated variant [150], [164]–[166]. These off-target, or secondary, mutations have been linked to compensatory and drug tolerance effects which can either reduce the fitness defects caused by the resistant variants, or allow the bacteria to handle stressful environmental conditions (e.g. a high drug concentration) better than the gWT. It was hypothesized that additional variants may have been co-selected with the resistance-associated mutation in at least some of the *in vitro* selected clones, which also may induce a phenotypic effect.

In order to determine such off-target variants, the whole genome of each mutant clone was compared to the gWT ancestor genome. Then, the dataset was filtered to include only variants with a >98% frequency in the genome, excluded all synonymous SNPs and repetitive genes, and included strains with only one additional variant aside from the resistance conferring mutation. With these filtering criteria, 20 different off-target variants were detected, co-selected with a resistance-associated mutation in 84 different mutant clones (Appendix D, Table D.1).

These mutations were selected after MFX exposure (with *gyrA* and *gyrB* variants), BDQ exposure (with *atpE* and *Rv0678* variants), and CFZ exposure (with *Rv0678*). The genes affected were associated with cell wall and cell processes (affecting 5 different genes), intermediate metabolism and respiration (4 genes),

information pathways (3 genes), lipid metabolism (1 gene), and protein regulation (1 gene). Interesting, off-target mutations were detected in six different conserved hypothetical proteins, which may be of particular interest as their functions are not well described (Appendix D, Table D.1). All information on genes and function was extracted from Mycobrowser (mycobrowser.epfl.ch).

It is not obvious whether these off-target mutations may influence fitness compensation, drug toleration, or other important cellular mechanisms as they have not yet been well characterized. In the following sections two mutant clones, with an off-target mutation, were characterized further and compared with the gWT ancestor, and resistant clone with a gWT off-target gene.

4.3.2 The mutation selection window of fluoroquinolone and bedaquiline resistance conferring mutations

The MSW is the defined drug range in which a mutation is selected and enriched; which is flanked by the lowest concentration the “minimum selection concentration” and the highest concentration, the MIC. The relative fitness is defined as the bacterial strain’s ability to reproduce and cause disease, this can be described in the lab by comparing the growth rate of the mutant clone with the gWT ancestor strain.

To define the MSW for clones with different mutations, several mutant clones and the gWT ancestor strain were exposed to different concentrations of antibiotics (MFX-related resistance with MFX, and BDQ with BDQ), and measured their growth every hour for 15 days (360 hours), in the automated BD Bactec™ MGIT system. In these experiments the growth capacity was measured as time until MGIT was positive (cut-off value of 400 units by internal MGIT system algorithm). The rate of growth was determined by hours until a positive culture was measured.

Experiments were first carried out with mutant clones which were selected after MFX exposure (Figure 4.3.1). Clones which harbored the most common mutations *gyrB* N499D, *gyrA* A90V and D94G, as well as *gyrB* E501D which was selected one time, were investigated. Additionally, to evaluate the effect of a secondary (off-target) mutation on relative fitness and the MSW, a clone with the mutation *gyrA* A90V with an additional variant, *ppgK* _266S, was evaluated (Appendix D, Table D.1). The mutant clones examined were genetically identical to the gWT ancestor, except for the defined variant(s). The drug concentration range tested was between 4 mg/L to 0.03 mg/L MFX, with all 2-fold dilutions evaluated in between (4, 2, 1, 0.5, 0.25, 0.12, 0.06, 0.03, and 0 mg/L MFX). After 82-84 hours incubation, positive cultures were first detected for all clones including the gWT ancestor, in tubes without antibiotics. At the

lowest drug concentration evaluated (0.03 mg/L MFX) all mutant clones began to outgrow the gWT ancestor ($p \leq 0.0053$) (Appendix D, Table D.2).

Interestingly, the experiments performed revealed that the growth rate of clones with different resistance-associated mutations began to diverge at MFX concentrations at or above 0.25 mg/L (Figure 4.3.1). The clones harboring mutations *gyrA* A90V or *gyrB* N499D exhibited an MIC of 1 mg/L MFX, although it appeared that the *gyrB* N499D clone reached positive growth more quickly than *gyrA* A90V mutant clone at 0.5 mg/L MFX exposure (86 hours faster on average), this was not significant ($p=0.988$, Appendix D, Table D.2). Clones with *gyrA* D94G or *gyrB* E501D mutations had an MIC of 2 mg/L, with *gyrB* E501D mutant growing more quickly on average than *gyrA* D94G, but this was not significant ($p=0.999$).

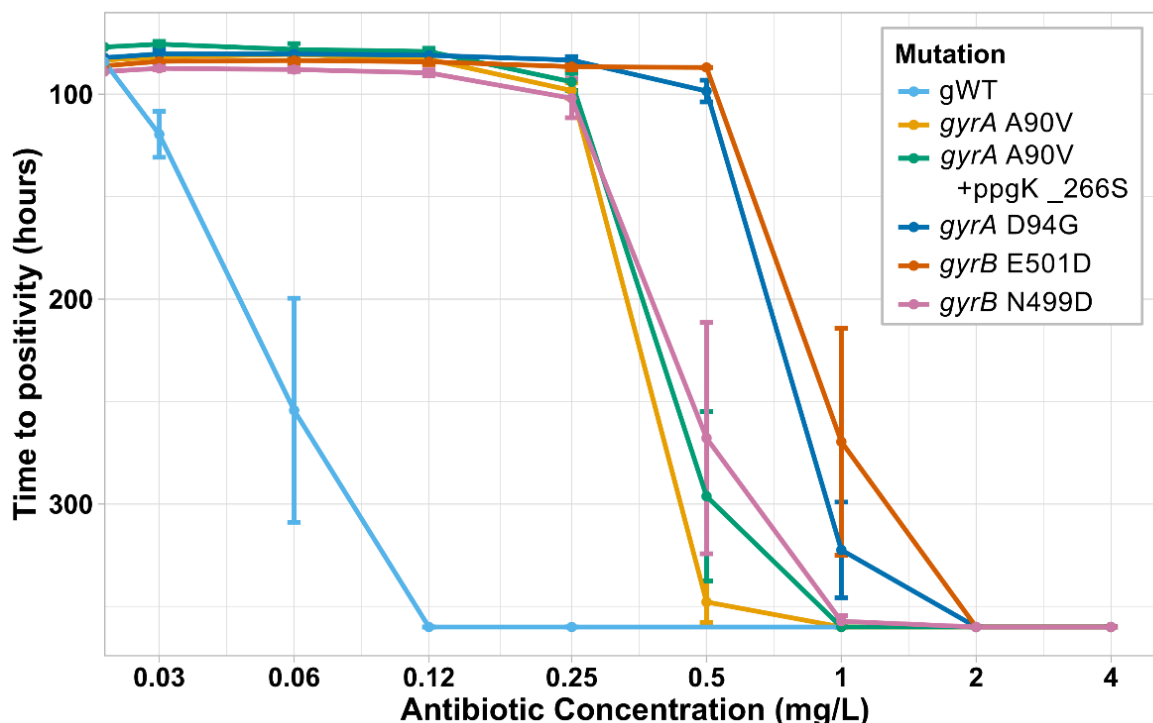

Figure 4.3.1: Mutant selection window of moxifloxacin resistant clones. H37Rv clones with resistance-associated mutations *gyrA* A90V, *gyrA* D94G, *gyrB* E501D, and *gyrB* N499D were selected from MFX evolutionary experiments. Each mutant clone was separately cultured in mycobacterium growth indicator tubes and growth was measured hourly, until time to positivity (fluorescence signal measured greater than or equal to 400 units) was achieved. Data is representative of two independent experiments, with a total of five biological replicates, including the genetically wild-type (gWT) ancestor clone.

Statistics: Two independent experiments were conducted including 2 or 3 biological replicates (5 values). Statistics were calculated as a nonparametric multiple contrast test (Kruskal) with a confidence interval of 95%. P-values in Appendix D, Table D.2.

Finally, when comparing growth characteristics of clones with a single *gyrA* A90V mutation with a clone with *gyrA* A90V in combination with the off-target mutation *ppgK_266S*, a slight difference in average growth rate at concentration 0.5 mg/L MFX (by 52 hours on average) was observed, and an MIC for both mutants at 1.0 mg/L (Figure 4.3.1). Although it appeared, on average, that the off-target mutation may give a growth advantage at higher concentrations, this was not significant ($p > 0.5$, Appendix D, Table D.2).

Next, several clones with BDQ resistance mutations were evaluated. Three clones with *Rv0678* mutations were evaluated, one with gene disrupting mutation R153_, one with the missense mutation S68G, and one with the *Rv0678* S68G plus an additional mutation in the downstream efflux pump gene as *mmpL5* A423D. Two clones with missense mutations in *atpE* were included: A63P and D28V. All clones were genetically identical to the gWT ancestor except for the indicated mutations. The drug concentration range tested for the *Rv0678* mutant harboring clones and gWT was between 8 mg/L to 0.12 mg/L BDQ with 2-fold dilutions evaluated in between (8, 4, 2, 1, 0.5, 0.25, 0.12, and 0 mg/L BDQ). Previous MIC testing indicated that *atpE* mutations highly enhanced the clone's BDQ MIC, therefore two higher testing concentrations were included, 30 and 15 mg/L BDQ.

Bacterial growth time to positivity was first detected, after 75-82 hours in the antibiotic free tubes. In the absence of antibiotics, the gWT outgrew all mutant clones, except *Rv0678* R156_ (Figure 4.3.2). The lowest drug concentration tested (0.12 mg/L BDQ) already suppressed the growth of the gWT and the *Rv0678* clones, increasing the time to detected growth to 100-150 hours. The MIC of the gWT ancestor was 1 mg/L BDQ, and both *Rv0678* mutant clones presented a 4-fold MIC increase, at 4 mg/L BDQ. It appeared that the clone with the S68G mutation, had a higher growth rate in most drug concentrations as compared to the gene disrupting mutation R156_. The *atpE* mutant harboring clones displayed virtually no reduction of growth, even at the highest tested concentration (Figure 4.3.2, Appendix D, Figure D.1). When comparing the *Rv0678* S68G mutant harboring clone to the clone with the same resistance mutation plus the *mmpL* A423D mutation, no difference in MIC and little difference in growth was observed. Although it appeared that the *mmpL* A423D mutation may have given a slight growth advantage on average, the standard deviation was large and overlapped between the clones. More experiments must be conducted in order to perform statistics (data represent one experiment with three biological replicates).

Figure 4.3.2: Mutant selection window of bedaquiline resistant clones. Resistance-associated mutations *atpE* A63P and D28V, *Rv0678* R156_ and S68G were isolated from BDQ evolutionary experiments. Each mutant clone was separately cultured in mycobacterium growth indicator tubes and growth was measured hourly, until time to positivity (fluorescence signal measured greater than or equal to 400 units) was achieved. Data is representative of one independent experiment, with a total of three biological replicates.

4.3.3 Bacterial fitness of resistance mediating mutations

In the following section, this study aimed to show the effect different resistance conferring mutations have on the relative bacterial fitness through direct growth competition experiments, between a mutation harboring clone and gWT ancestor. The same H37Rv MFX and BDQ resistant clones evaluated in the previous section were investigated, except *gyrB* N499D which was excluded due to culturing issues. The experiment was carried out by inoculating a culture with about 50% of the gWT ancestor and 50% the resistant clone, after 14 days of growth (including one culture passage) the final frequency of the resistant allele was determined by WGS.

After the competition experiments, the frequency of *gyrA* mutations D94G increased by an average of 4.2% ($p=0.15$) over the gWT allele (Figure 4.3.3, Appendix D, Table D.3). The A90V mutation frequency increased on average by 3.67% but there was not a statistical difference ($p=0.352$). Further the frequency

of *gyrB* E501D increased by 1.1%, and was also not statistically significant ($p=0.923$). Since there was a slight increase in the frequency of these alternative alleles, it is indicated that they are highly competitive with the gWT and likely do not induce a fitness defect. Finally, the additional variant *ppgK* _266S with *gyrA* A90V, did not appear to give the clone a growth advantage over the gWT ($p=0.074$) or the single A90V mutant harboring clone ($p=1.0$).

Figure 4.3.3: Allele frequency of moxifloxacin resistance harboring clones. Each mutant clone was co-cultured with the genetically wild-type (gWT) ancestor at a 50:50 ratio. After 14 days (and one culture passage) of growth, the frequency of the resistant variant in the total population was determined by whole genome sequencing. Change in allele frequency was determined by the percent increase or decrease as compared to the starting mutant to gWT ratio.

Statistics: Two independent experiments were conducted, with 4-6 biological replicates total. Statistics was calculated as nonparametric multiple contrast test (Kruskal) with a confidence interval of 95%, p-values between mutant and gWT, Appendix D, Table D.3: * $p<0.05$, ** $p<0.01$, *** $p<0.001$

Competition experiments were repeated with the same BDQ resistant mutants evaluated in the previous section (Results 4.3.2). Interesting, 4.7% and 5.5% decrease in allele frequency was observed, for *atpE* mutations A63P ($p=0.006$) and D28V ($p=0.0038$) respectively (Figure 4.3.3, Appendix D, Table D.4). The

Rv0678 mutation S68G indicated a 0.75% reduction in allele frequency, which was not statistically significant ($p=0.968$). The gene disrupting mutation *Rv0678* R156_, presented an average decrease of 4.5% ($p=0.053$). Finally, the mutant which harbored an additional variant (*Rv0678* S68G plus *mmpL* A423D), did not appear to give a growth advantage over the gWT ($p=0.099$) or the single A90V mutant ($p=1.0$).

Figure 4.3.4: Competitive relative fitness of bedaquiline resistance harboring clones. Each mutant clone was co-cultured with the genetically wild-type (gWT) ancestor at a 50:50 ratio. After 14 days (and one culture passage) of growth, the frequency of the resistant variant in the total population was determined by whole genome sequencing. Change in allele frequency was determined by the percent increase or decrease as compared to the starting mutant to gWT ratio.

Statistics: Two independent experiments were conducted, with 4-6 biological replicates total. Statistics was calculated as nonparametric multiple contrast test (Kruskal) with a confidence interval of 95%, p-values between mutant and gWT, Appendix D, Table D.4: * $p<0.05$, ** $p<0.01$, *** $p<0.001$

4.3.4 Non-canonical mutations potentially implicated in bedaquiline/clofazimine resistance

As previously detailed, WGS performed on the Illumina® platform does not result in a mutation call in all clones derived from single colonies grown on selective media, and although 13 clones presented an elevated MIC to either BDQ or both BDQ and CFZ drugs (Table 4.3.1). Nine clones harbored mutations in

other “off-target” genes, yet four clones were genetically identical to the gWT ancestor based on standard Illumina® WGS data analysis.

Table 4.3.1: Selected mutants with elevated bedaquiline (and clofazimine) minimum inhibitory concentration, with no detectable resistance-associated mutations. Several selected mutants harbored no mutation in *Rv0678*, *atpE*, *pepQ* or *Rv1979c*, but presented an elevated minimum inhibitory concentration (MIC) to bedaquiline (BDQ), and mostly clofazimine (CFZ). Three mutants were selected for de novo assembly (*) by single-molecule real-time long-reads on PacBio® Sequel2 platform.

Off-target gene summary:

Gene	Gene Name	Gene Annotation	Functional category
<i>Rv0195</i>	-	Possible two component transcriptional regulatory protein (probably LuxR-family)	Regulatory protein
<i>Rv1890c</i>	-	Hypothetical protein	Conserved hypothetical protein
<i>Rv1330c</i>	<i>pncB1</i>	Nicotinic acid phosphoribosyltransferase PncB1	Intermediary metabolism and respiration
<i>Rv3312c</i>	-	hypothetical protein	Conserved hypothetical protein
<i>Rv1860</i>	<i>apa</i>	Alanine and proline rich secreted protein Apa (fibronectin attachment protein)	Cell wall and cell processes

To investigate possible resistance mechanisms of these clones, the mutations found in “off-target” genes were examined. These genes were associated with transcriptional regulation (*Rv0195*), nicotinic acid phosphoribosyltransferase metabolism (*Rv1330c*), cell wall processes (*Rv1860*), and conserved

hypothetical proteins (*Rv1890c* and *Rv1860*) (Table 4.3.1). These mutations were not seen in other clones except for *Rv1890c* R119H, which was co-selected with resistance-associated mutations in *gyrB* and *Rv0678* (Appendix D, Table D.1). A search of the >40,000 strain database of the Molecular and Experimental Mycobacteriology Research Group (Research Center Borstel), indicated that none of these mutations were found in clinical isolates, and therefore were most likely not linked with BDQ/CFZ resistance.

Next, the short-read sequencing alignment was explored in detail using IGV software (Broad Institute). In the sequencing alignment, a large break (or scar) in the coding region of *Rv0678* was present (Figure 4.3.5). This break, led to the hypothesis that there was likely a large deletion or insertion, which was not detected by standard short-read sequencing data analysis (one of the limitations of short-read synthesis sequencing). To test this hypothesis, three clones were selected for long-read sequencing on PacBio® Sequel2 system, followed by *de novo* assembly (Table 4.3.1 *). PacBio® Sequel2 sequencing allows for an increase of sequencing read length from 150 base pairs to about 20 kilo-base pairs, thus enabling an efficient detection of large-scale genomic modifications.

Figure 4.3.5: Short-read sequencing alignment of a genotypically susceptible (but phenotypically resistant) clone. View of the aligned reads of a bedaquiline clone (sequencing ID: LBA-83) which, through Illumina® short-read sequencing, did not appear to harbor a mutation in any known BDQ/CFZ resistance conferring genes. At position 779,061-779,063, a break occurred in the sequencing data reads and alignment.

A *de novo* assembly was produced using PacBio® SMRT® Link software, which generated a closed Mtb genome with two assemblies, with one and four contiguous sequences (Figure 4.3.6). All assemblies covered more than 99.9% of the reference genome (NC_000962.3). All three clone assemblies showed a large-scale sequence re-arrangement with the borders at position 779,073 (*Rv0678* coding sequence) and 3,552,584 (intergenic region) and flanked by a transposase open reading frame (*IS6110*). A 2.5Mb fragment was inverted and thus split the *Rv0678* gene into halves (Figure 4.3.6).

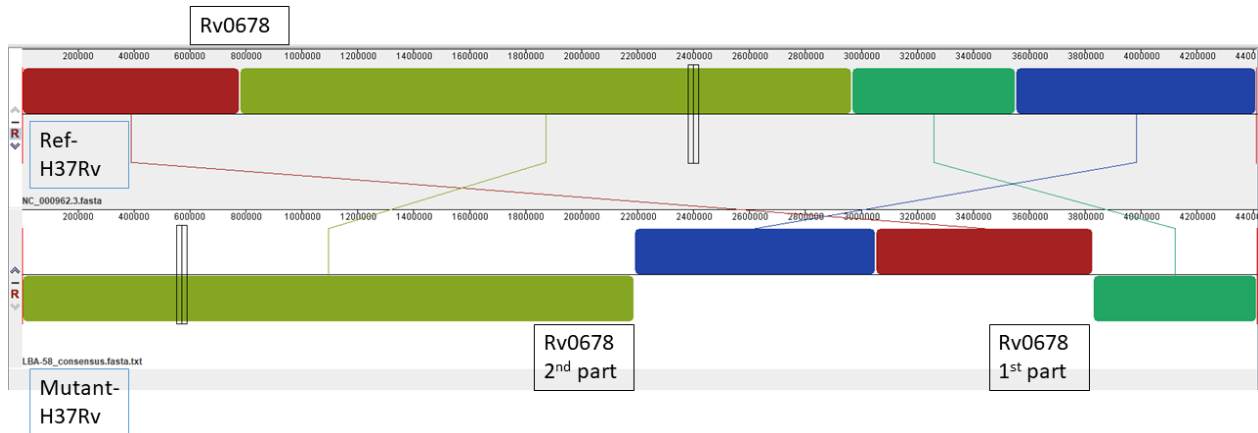

Figure 4.3.6: Large-scale gene rearrangement in *Rv0678* gene. De novo assembly through PacBio® SMRT® Link software indicated large-scale sequence rearrangement in *Rv0678* at positions 779,073 coding sequence and 3,552,584 intergenic regions. Adapted from Sonnenkalb *et al.* 2021 [140].

5. Discussion

Bacteria of the Mtb complex are some of the oldest known bacterial pathogens, inflicting humans for the past 40,000-70,000 years [1], [167]. Although there have been major advancements in antibiotic treatments, TB continues to be the most deadly infection over the last decades on a worldwide level, killing over 1.5 million people every year [168]. Despite a steady decrease in TB incidence (Figure 2.1), drug resistant and even MDR-Mtb strains are rising and spreading world-wide, which could impede global efforts to eradicate this disease (Figure 2.2) [168].

In order to combat these persistent organisms, researchers are putting more focus on understanding evolutionary trajectories which allow Mtb strains to develop drug resistance and spread. This is accomplished by experimental modeling, intra-patient evolution under treatment, and on global scales through analysis of large strain collections (including transmission chains). In this study, the main aims were to elucidate factors which affected intra-patient resistance evolution, to establish and evaluate a new sub-MIC evolution model for studying resistance development *in vitro*, and to further investigate resistance mechanisms and the MSW to important drugs used in MDR-TB treatment. The main results obtained from this study are discussed in the following sections, as well as final conclusions and outlook.

5.1 Elucidating factors of intra-patient resistance evolution of a *Mycobacterium tuberculosis* complex bacterial infection

As a paramount example for a failing MDR-TB regimen and ongoing resistance acquisition, serial isolates were investigated from a single patient while under longitudinal MDR-TB treatment. This patient suffered from five distinct infectious TB episodes, spanning 56 years of their life, with over 27 years of applied treatment. The final treatment episode lasted 18 years and was the focus of this analysis. This case was retrospectively reviewed, using molecular techniques to evaluate bacterial isolates collected throughout that period, compare with an in-depth patient treatment history and phenotypic testing data (i.e. DST). While several other studies have been conducted evaluating intra-patient strain evolution through analysis of serial isolates [81], [83]–[85], [169], [170], this study is one of the longest treatment histories ever published, in which a single strain acquired resistance to every available drug [87].

This extreme example of a failing treatment with multiple treatment episodes was characterized by three major determinants: inadequate/inefficient drug combinations, co-existing heteroresistant Mtb

subpopulations, and the acquisition of off-target mutations resulting in strain populations with likely enhanced fitness. To better understand the evolution of this infectious Mtb strain, selective sweeps linked to phases of ineffective treatment regimens were evaluated, heteroresistant bacterial populations (the adaptive landscape) in different treatment phases were tracked, and the effect of compensatory/tolerance-associated mutations on the selection of particular mutant populations was considered.

5.1.1 Failing treatment regimens foster resistance selection

One of the most important factors in successful TB treatment (for treating any pathogen related illness), is administering an effective treatment regimen. Even susceptible Mtb infections require a long-term treatment of a four-to-six month regimen, including four antibiotics [171]. The WHO's consolidation guidelines on treating MDR-TB infections includes at least three effective drugs from group A and one from group B (Table 2.2) [172]. As an infectious Mtb strain gains more resistances, treatment design becomes more complicated and longer. This situation results in a long-term selection pressure, which in combination with weak drug combinations, potentially facilitates further resistance evolution in patients.

The patient investigated here suffered from an exceptionally complex TB infection and course of treatment with frequent changes in drug regimens and final acquisition of seven resistances. The final treatment period analyzed here, started already with an MDR strain, resistant to INH, RIF, EMB, and SM. The first bacterial isolate which was sequenced, harbored resistance-associated variants to INH, RIF, PZA, PTH, SM, PAS, and CS/TRD (Figure 4.1.1, Appendix B, Table B.2). Over thirteen years of treatment, the rise and fixation of mutations conferring FQ, EMB, LZD, CPR, and CRP/AMK/KAN resistances was observed. Considering WGS based resistance predictions, there was only a two month period in which three active drugs were included in the regimen, falling short of WHO treatment guidelines (Figure 4.1.1) [172]. More alarmingly, there were over 85 months in which only one active drug was applied, and 54 months in which no active drugs were administered (Appendix B, Table B.1.). Phenotypic and genotypic resistance predictions were not always congruent in this study, although both indicated over 13-years of suboptimal therapy design. Accordingly, it became clear that poorly designed treatment therapies were responsible for selection of subpopulations with additional resistance mutations in several phases of ineffective treatment regimens.

As a likely consequence of this long-term inefficient therapy, the infecting Mtb strain went through multiple genetic bottlenecks which facilitated the fixation of additional resistance mediating mutations, in a stepwise manner. For example, nearly 12 months of OFX mono-therapy coincided with the rise and fixation of the FQ resistant variant *gyrA* D94G in the population (Figure 4.1.1, Appendix D, Table D.1). This was followed by LZD then AMK resistance acquisition, after 20 months and 7 months of drug application, respectively. In line with previous studies, even dating back to the development of the first anti-TB drugs [40]–[42], the result obtained here underline the fact that MDR-TB regimens with just one or two effective drugs leads to rapid resistance development, as described in at least three other studies [83], [169], [173]. Furthermore, it has been recently confirmed that 3 to 4 drugs are required to reach high cure rates in patients with MDR-TB infections [174].

Still, it is not evident why ineffective drugs were included in this patient's treatments, even after resistant phenotypic results were provided. Unfortunately, information on the decisions of the treating physicians was not noted, and therefore one can only speculate why the treatments were designed in this way. Even so, there were not many treatment options left for this patient, except for strategies like increasing drug dosage [175]. Finally, it was clear that it took months for these resistance conferring mutations to rise to fixation, therefore a deeper analysis into the sequencing data was performed to understand the adaptive landscape and potential heteroresistant populations.

5.1.2 The adaptive landscape and heterogeneous populations

To define the selection and evolution of the clonal subpopulations in detail, thirteen serial isolates were analyzed for the presence of low- and high-frequency subpopulations. Heteroresistant populations were confirmed if at least two subpopulations with resistant allele(s) with/without the gWT allele, were present in a given sample. The analysis describes a highly heterogeneous intra-patient evolution, with several instances of competing clonal subpopulations and an evolutionary arms race for selection and fixation into the population. Core genome multi locus sequence typing, confirmed that all subpopulations were of the same strain, and that reinfection or a mixed infection with two Mtb strains could be ruled out (Figure 4.1.2) [176].

The diverse adaptive landscape consisted of several instances of heteroresistant clonal subpopulations, which arose and fluctuated while under antibiotic exposure, even in the absence of the antibiotic in one case. Similar data on the rise and fixation of resistance mutations in patient-derived strains under

longitudinal MDR-TB therapies, have been observed in other studies through the analysis of serial isolates [81], [83]–[85], [169], [170]. However, no other studies have considered a comparable treatment duration. In line with the data obtained here, intra-patient heterogeneity can be clearly associated with poor clinical outcomes when linked with poorly designed treatment regimens [173], [177].

A selection pressure is necessary for the adaptation of Mtb bacteria, in response to environmental changes such as antibiotic exposure. Over a 14-month period, while under CPR treatment, two subpopulations with different frameshift mutations in the *tlyA* gene arose and competed until one was ultimately selected. One would assume that frameshift mutations in a single gene have a similar (if not equal) effect on the phenotype. This data indicated the effect of a particular mutation on the phenotype, such as resistance level and/or fitness, is not solely accountable for the selection of a mutant subpopulation. In this example, the finally selected frameshift mutation was co-selected with an AMK/CPR/KAN resistance-associated mutation, since the both variants concurrently increased to 100% in the same isolate. Thus, resistance development to a second drug finally facilitated the selection of another resistance associated allele.

The selection of subpopulations with a particular mutation from a heterogenous population was occurring while under antibiotic treatment. Surprisingly, heteroresistant subpopulation competition was also observed with different mutations in the absence of the respective resistance-associated drug. For example, competition between three *Rv0678* mutations over a 37-month period was occurring at low-frequencies ($\leq 70\%$) ultimately ending in the loss of these variants. This observation is especially interesting as the two drugs most associated with mutations in *Rv0678* are BDQ and CFZ, yet neither was included in any of the treatment regimens (Appendix B, Table B.1) [76], [178]. *Rv0678* is an efflux pump regulator, which has only been associated with BDQ and CFZ, and cross-resistance with other important anti-TB drugs have yet to be explored. However, in a recent study, it was reported that an outbreak strain in Eswatini carried mutation in *Rv0678* even though BDQ and CFZ were not used in the country at the time the strains were isolated [179]. This points to other selection pressures that may select for mutations in *Rv0678*, that later confer resistance to BDQ and CFZ. Here, *in vitro* derived *Rv0678* mutants were evaluated for cross-resistance to DLM and LZD, but no resistance was detected (Table 4.2.6). Thus, further experiments are needed to detect possible unknown mechanisms of *Rv0678*-mediated resistance or virulence, that potentially lead to selection of *Rv0678* variants in Mtb strains naïve to BDQ and CFZ.

One pitfall of this study is the retrospective nature. These isolates were acquired from sputum and sub-cultured, long before DNA was extracted for WGS. Also, sputum samples are not an optimal method for

detecting heterogeneous populations. A recent study which analyzed lung resections from TB patients found that polyclonal infections were present in 7 out of 18 (39%) individuals, an increase from the 5% of mixed infections determined from sputum samples [180], [181]. For this study all samples were sub-cultured, thus causing another influence on the frequency at which a mutation was detected. Since resistance mutations can reduce bacterial fitness, a resistant allele may have decreased during cultivation if it had not yet reached fixation (nearly 100% population frequency) [165], [182]. The best solution to overcome these potential problems with sub-culturing is to directly sequence sputum, which at present can only be accomplished by amplicon deep sequencing [183], [184]. This methodology was not possible in this study, as sputum samples were not preserved and only bacterial stocks were available.

Despite these technological pitfalls, a diverse adaptive landscape of competing heteroresistant populations was observed, always arising before a single resistance-associated variant reached fixation. Next, this study focused on the analysis of off-target mutations that were co-selected at several time points throughout the complicated treatment duration.

5.2.3 Off-target mutations implementing putative compensatory and tolerance mechanisms

An important topic which has become more prevalent as our scientific knowledge grows, are off-target mutations which potentially ameliorate the fitness of a resistant clone, i.e. compensatory mutations [185], [186]. The compensatory effect of *rpoC* mutations following *rpoB* mutations mediating RIF resistance has been the most well described compensatory mechanism in *Mtbc* strains in both, *in vitro* studies and molecular epidemiological studies [164], [187]–[190]. Further genes linked to compensatory evolution include: *rpoA* with *rpoB* (RIF), *oxyR'-ahpC* with *katG* (INH), *ubiA* with *embB* (EMB), *pncB2* with *pncA* (PZA), *thyX-hsdS.1* with *thyA*, and *Rv0565c* with *ethA* (ETH/PTH), to name a few [164], [191]–[194].

The gene *Rv0565c* was recently identified as coding for a compensatory enzyme which activates *inhA* when the primary activating enzyme *ethA* is disrupted [193], [194]. Not only are the *ethA* and *Rv0565c* genes coding for enzymes which activate *inhA* in the bacteria, but can also activate PTH/ETH prodrugs (at likely variable degrees) [193], [194]. Mutations in *Rv0565c* have only been detected concurrently with *ethA* mutations in clinical isolates, and *in vitro* experiments have shown that its over expression renders the strain more sensitive to PTH/ETH [194]. Indeed, the mutation *Rv0565c* C298R was detected following the baseline mutation *ethA* 89 del a after intermittent PTH exposure. The fixation of this mutation coincided with a resistant phenotype, so it is probable that this enzyme was compensating for the loss of *ethA*, and

involved still in PTH/ETH activation. Therefore, the compensatory effect of a functional *Rv0565c* may have been ameliorated with this additional mutation, and allowed the bacteria to be more tolerant or resistant to PTH/ETH (Figure 4.1.1).

Drug tolerance is an important survival mechanism, which unlike resistance is not specific to one class of drugs, does not affect the MIC, but extends the necessary time needed for bacterial killing [150], [166], [195]. Although tolerance mechanisms are mainly occurring on the transcriptional level, Hicks *et al.* described mutations in transcription factor *prpR* (*Rv1129c*) as potentially enhancing drug tolerance to a multitude of anti-TB drugs [150]. This hypothesis is in line with this study, as at month 92, the first appearance of the variant *prpR* F334L was observed, which was fixed in the population at month 108 (Appendix B, Table B.2). During that period the strain was exposed to PZA, PTH, CPR, TRD, and LZD, and potentially, the observed *prpR* mutation allowed the strain to tolerate a higher concentration of antibiotics, but this must be further investigated experimentally.

Taken together, the data obtained demonstrated that the evolution of a highly resistant, untreatable infection was a result of poorly designed ineffective treatment regimens in combination with hetero-resistant subpopulations that allowed for selection of the most resistant subpopulations, but is further aided by acquisition of additional compensatory and tolerance mechanism that likely fueled this Mtb strain's evolutionary trajectory.

5.2 The impact of sub-inhibitory drug exposure on *Mycobacterium tuberculosis* bacteria

Treatment of TB, especially drug resistant or even MDR-TB, is highly complex and lengthy [171], [172]. This situation further provides a long-term selection pressure which likely fosters the rise of heteroresistant populations in the patient as described above [87]. Another point is that anti-TB drugs are unevenly distributed in infected organs and cellular compartments such as granulomas comprising different cell types such as macrophages, and neutrophils, and can also have a central necrotic zone that is particularly hard to penetrate by several drugs (Figure 2.3)[111], [112], [116], [152], [153], [196]. This may lead to large differences in drug concentrations in different sites of the disease, also resulting in below MIC concentrations, even if the drugs are administered in the right dose [116], [197], [198]. To which extent such situations can lead to the selection of resistant subpopulations has not been well defined for Mtb bacteria [199].

Most *in vitro* selection experiments which have been utilized to induce spontaneous mutations, i.e. *de novo* evolution, have been carried out at high antibiotic concentrations (at or above the MIC) [127], [136]. Some limitations of these experiments are the tendency to select for variants not commonly found in patients, or entirely miss clinically relevant mutations with low-level resistance profiles [75], [137], [200], [201]. Therefore, this study attempted to develop a new sub-MIC evolution model with Mtb bacteria. Based on the work of Gullberg, Liu, Andersson, and Hughes, this sub-MIC evolution model was designed, which included long-term, sustained exposure of sub-MIC antibiotic concentrations of the bacteria in liquid culture [132]–[134]. This model was also hypothesized to better reflect the intra-patient situation, by not only providing a drug selection pressure, but also competition with heterogeneous bacterial populations in order to select more fit, clinically relevant mutations.

5.2.1 Sub-inhibitory drug exposure selects resistance conferring clones

First, the sub-MIC evolution model was established for MFX as a proof of concept, since it is a well-studied and superior FQ MDR-TB drug. Then this model was applied to one of the newest drugs on the market, BDQ and the repurposed drug CFZ; drugs which are known to also have a cross-resistance mechanism via mutations in *Rv0678* [73], [163], [202]. To explore a range of antibiotic selection pressures, the bacteria were exposed to the four highest tolerable drug concentrations, with a 2-fold dilution between each concentration, starting at 1:2 the MIC and decreasing (Figure 4.2.3). Minimal growth inhibition was

important and enabled consistent drug dosing, which fostered bacterial sampling that was analyzed throughout the experiment.

For all three drugs, a dose dependent increase of mutant populations was observed, even short-term (four days) exposure of half the MIC resulted in a significant increase in the mutant population, as compared to the antibiotic free control population. This was an important observation, as it is difficult to maintain high levels of antibiotics in patients, and this study showed that reduction of drug concentrations to half of the MIC caused a positive selection of resistant clones [203], [204]. Long-term drug exposure also revealed that drug concentrations as low as 1:16 the MIC can select for resistant populations which significantly increased as compared to drug-free conditions. This data allowed a first insight into the MSW of important MDR-TB treatment drugs and demonstrated that resistant populations could be selected at intra-patient niches, where drug concentrations are low/reduced [152], [196].

5.2.2 Sub-minimum inhibitory concentration evolution model captures a wide diversity of resistance associated mutations

After the positive selection of resistant populations was observed at concentrations far below the MIC, it was investigated if the mutations obtained were diverse, what their impact on resistance levels was, and their potential clinical significance. To address this, single clones were selected by picking mutant colonies from the antibiotic supplemented agar plates. These clones were grown in antibiotic-free culture, and screened for increases in MIC by REMA. All clones which were picked presented an elevated MIC and underwent WGS to determine the resistance associated mutation. In total, 140 MFX mutant clones were selected and characterized, and 215 clones from BDQ/CFZ selection experiments.

Of the clones which were cultivated under MFX exposure, WGS revealed three unique variants in *gyrB* and seven in *gyrA*. All MFX clones presented at least an 8-fold MIC increase, as compared to the gWT. The most common variants selected in *gyrA* were A90V and D94G, which are also most often found in clinical isolates with FQ resistance profiles [142], [156]. Other common variants seen in patient-derived strains recovered were - *gyrA* S91P and four variants affecting codon D94 of *gyrA* [205], [206]. However, many *gyrB* variants were also selected (20% overall), which reflected less the clinical situation, as *gyrB* mutations are less often seen in patient isolates [206], [207]. Even so, all of the mutations selected fell within the QRDR (Figure 4.2.9) [156], [208].

In order to implement a more unbiased approach for variant detection, all mutants growing on MFX-supplemented agar plates were pooled together and WGS deep sequencing was performed (coverage depth average of 595x), to detect all *gyrA* and *gyrB* variants at a frequency $\geq 1\%$ in a given population (Table 4.2.1). In this approach, five additional mutations in *gyrB* were identified, two of which implemented codons outside of the QRDR (Figure 4.2.9). No additional *gyrA* variants were found. Again, a higher rate of *gyrB* mutations of 20% was observed, whereas mutations in this gene affects only 1-2% of FQ resistant clinical strains [206]. All together, these results confirmed that below MIC concentrations select for relevant resistance mutations and that this *in vitro* design is a good model for selecting mutant clones with clinically relevant mutations, since the majority of the variants selected have been reported also in resistant, patient-derived isolates [142], [156], [206]. Therefore, similar investigations were continued with other important anti-TB drugs.

Next, this sub-MIC evolution model was applied to BDQ and CFZ, drugs of which mechanisms of resistance are not well understood. These drugs are known to have cross-resistance mechanisms through mutations in *Rv0678*, but also likely by mutations in *pepQ* and *Rv1979c* [77], [201], [209], [210]. Resistance to BDQ can also arise due to mutations in the gene coding for its target, *atpE* [75], [160], [201], [211].

BDQ is currently the most important drug for the treatment of MDR/XDR-TB as it has potent bactericidal activity with a novel mode of action - inhibition of ATP synthase [75]. Since BDQ's widespread use in 2014, only three studies have reported BDQ resistance due to an *atpE* mutation in patient-derived isolates [140], [160], [211]. Most resistance in patients is linked to mutations in *Rv0678*, a gene which regulates the expression of the *mmpS-mmpL* efflux pump [76]. CFZ is also an important drug in treating MDR-TB, the precise mode of action remains unknown, but most resistance to CFZ has also been linked to mutations in *Rv0678* [159], [212], [213]. Of the 215 mutant clones selected from either BDQ- or CFZ-supplemented agar plates in this study, 68 unique variants were reported, the largest diversity of mutations reported in a single selection study [74], [136], [212], [214]–[216]. Previous studies selected mutant clones at high BDQ or CFZ concentrations (more than twice the MIC), but did not generate a high quantity or diversity of variants [136], [216], [217]. Here, mutant colonies were selected from both high and low concentration plates, with instances of the same mutant allele growing at both concentrations (the MIC and 2x the MIC) (Appendix C, Table C.9).

In line with studies on patient-derived BDQ/CFZ resistant strains, a minority of mutants (only 18) were obtained that harbored a variant in *atpE*, with five unique mutations selected. As previously mentioned, only three studies have reported BDQ resistance due to an *atpE* mutation in patient-derived isolates [140],

[160], [211], and less than 1% of BDQ resistance seen in patients is attributed to *atpE* mutations [140], [213]. As in previous patient and *in vitro* studies, major increases in the BDQ MIC were observed for clones harboring an *atpE* mutation, which often exceeded the concentrations tested in both REMA (at least 4-fold or higher than the gWT), and MGIT - growing at the highest concentration tested (Tables 4.2.5, 4.2.6). Interestingly, two clones also presented an elevated MIC to CFZ (2-fold above the gWT) in both REMA and MGIT assays. Collateral resistance between BDQ and CFZ has not been established in bacteria with an *atpE* variant, although CFZ testing has been rarely reported in such strains [140], [160], [212].

Furthermore, congruent with BDQ/CFZ resistant patient-derived strains, the majority of variants selected in this study implicated the efflux regulator protein Rv0678. Indeed, more than 99% of *in vitro* and patient-derived isolates harbor variants throughout this gene (Appendix C, Table C.11). The clones selected from single colonies which had a variant in *Rv0678* presented a 2- to 16-fold increase in BDQ MIC and up to a 12-fold increase to CFZ. Of the selected mutant clones, 184 harbored a variant in *Rv0678*, with 25 unique variants selected after BDQ exposure, 31 after CFZ, and eight which were selected in both BDQ and CFZ experiments. Deep sequencing on the total mutant population of a given selection plate was again performed as a less-bias approach to detect additional variants which were not selected as a single colony. From this, no additional *atpE* variants could be identified, but an additional 39 variants in *Rv0678*, and thirteen variants in the gene *pepQ* were determined.

Interestingly, while mutations in *pepQ* or *Rv1979c* could not be detected in clones derived from single colonies, eight non-synonymous and five synonymous SNPs in *pepQ* were detected by the less-biased population (deep) sequencing approach after CFZ exposure (Appendix C, Table C.8, Figure 4.2.10). This may be caused by a competitive growth defect which mirrors the situation in patients, as a clear link between these mutations and failing TB-treatment has not been well established. Based on current knowledge, *pepQ* mediated resistance has only been clearly linked to CFZ resistance from *in vitro/vivo* selection experiments, but not in patients [77]. So far, only one study implicated *Rv1979c* in BDQ/CFZ cross-resistance, and one other study presented CFZ resistance in patients [163], [218]. Accordingly, it appears that the long-term sub-MIC evolution model better reflects the clinical situation leading to the identification of mutations of high clinical relevance.

However, mutations in *Rv1979c* may be more relevant than previously thought, as the large clinical Mtb strain collection provided by CRYPTIC included four *Rv1979c* variants (in 35 isolates) linked to moderate-to-high BDQ/CFZ resistance (Appendix C, Table C.10). When the CRYPTIC strain collection was searched for

pepQ variants, only susceptible or borderline-resistance phenotypes were consistently reported (Appendix C, Table C.10).

Taken together, the data obtained in this thesis showed that the sub-MIC evolutionary model has high potential for determining resistance variants to TB drugs. Still, this model also involves a potential selection bias and the ratio of selected mutants may not always reflect the situation in the host and in drug resistant clinical strains observed in different parts of the world. However, the data obtained indicate that this sub-MIC evolution model better reflects the clinical situation than other “high MIC selection” models. Taking all evidence together, this model could be applied to less studied anti-TB compounds and new drugs to define resistance mechanisms and enhance our capacity for molecular resistance prediction.

Based on the obtained data on resistance mutations, this study proceeded to further develop an advanced mutation catalogue for the prediction of BDQ/CFZ drug resistance in clinical isolates, e.g. from genome sequencing data.

5.2.3 Developing a mutational catalogue for bedaquiline and clofazimine

As comprehensive molecular approaches to define drug resistances such as WGS, and targeted genome sequencing such as Deeplex[®], are becoming more affordable and accessible even in high incidence, low-income settings, valid catalogues for interpretation of WGS data are urgently needed. The detection of high-confidence resistance associated SNPs can predict drug susceptibility to first-line and most secondary drugs, to a degree which can be implemented in the clinic [91]. For the first time, the WHO released a respective mutation catalogue “Catalogue of mutations in *Mycobacterium tuberculosis* complex and their association with drug resistance” with validated resistance mutations to inform genome sequencing based resistance testing [219]. After rigorous screening and quality control steps, 38,215 isolates were included to develop the WHO’s catalogue, including 15 different anti-TB drugs. However, no BDQ/CFZ mutations met the criteria to be included in this report, due to the low-frequency of specific mutations in the dataset, MIC values which were too close to the critical concentration, and the phenotypic methodology of the only large study was not sufficiently verified (CRyPTIC).

To tackle this critical need of developing a respective mutation catalogue, the combination of high-quality MIC data from standardized phenotypic DST and WGS data analyzed with a standardized pipeline is needed. As first steps to compile a BDQ/CFZ mutation catalogue, the data generated from the *in vitro* experiments was combined with a large strain collection dataset provided by CRyPTIC and organized into

a user-friendly variant list (Appendix C, Table C.11). In order to get a full spectrum of potential variants implicated in resistance, mutations identified in 25 published studies were also included in this catalogue, although the work of others may not have followed this study's stringent methodology for DST. Altogether this catalogue included 247 unique mutations across four genes. In relation to BDQ, 159 represent a resistant, 30 a borderline, 26 a susceptible, and 15 a variable phenotype. For CFZ phenotypes, 117 were resistant, 25 borderline, 23 susceptible, and 15 were variable.

This first comprehensive catalogue of variants associated with resistance or susceptibility of BDQ/CFZ is a major achievement towards genome sequencing based resistance prediction. Indeed, 94 Mtbc strains in the CRyPTIC collection with mutations in *Rv0678* were classified as susceptible, 39 of which were hypersusceptible (≥ 0.015 mg/L BDQ MIC), warranting further investigation.

5.2.4 Hypersusceptible phenotypes in patient strains with *Rv0678* mutations may be linked to epistasis

It is important to consider that not all mutations in resistance-associated genes lead to resistance and benign mutations can be prevalent in resistance-associated genes [149]. Such mutations do not have an effect on the bacterial resistance phenotype, but may be misclassified as causing resistance, especially in a scenario where no curated mutation catalogue based on robust genotype/phenotype data is available. Another situation, which can affect bacterial sensitivity, is the presence of so-called epistatic mutations, i.e. mutations, often in a separate gene, which affect the phenotype caused by another mutation. These off-target mutations can mitigate the effect of the resistance mutation and can render Mtbc strains hypersusceptible to particular drugs [220], [221]. Vargas *et al.* has proposed that variants in the *mmpS5*-*mmpL5* efflux pump genes might counteract the resistance associated effect of *Rv0678* mutations by causing a malfunction or inhibition of the efflux pump [220]. Therefore, the genomes of the CRyPTIC strain collection were inspected for co-occurring *Rv0678* and *mmpS5* (*Rv0675c*) or *mmpL5* (*Rv0676c*) mutations.

Overall, 94 strains with a *Rv0678* variant were present in the CRyPTIC strain collection with a susceptible phenotype to BDQ (MIC < 0.12 mg/L), 39 of which were hypersusceptible (MIC ≤ 0.015 mg/L). Of the 94 isolates with a low BDQ MIC, 37 (39.4%) harbored a mutation in *mmpS5* or *mmpL5*. In order to ascertain the effect of an additional *mmpS5*/*mmpL5* variant, one must compare clones with the same *Rv0678* mutation that also harbor a gWT or mutated *mmpS5*/*mmpL5* gene. The most abundant example for comparison in this dataset included 23 isolates which harbored the mutation *Rv0678* 192 ins g, of which 20 were categorically susceptible to BDQ with a corresponding *mmpL5* mutation. However, one of the

three isolates with no *mmpL5* mutation also had a susceptible phenotype (MIC 0.03 mg/L BDQ), the other two strains were borderline (MIC 0.12 mg/L BDQ) and resistant (MIC 0.25 mg/L BDQ). This sample may be indicative of an epistatic correlation between mutations in these genes in this dataset, but extrapolating a clear connection is too speculative. Although we can assume that the *mmpS5-mmpL5* efflux pump must be active for *Rv0678* mutations to be effective, the functionality of the efflux pump was not verified in these strains.

Taken all evidence together, a clear-cut conclusion on epistatic relationships cannot be made based on the findings obtained. However, considering the wide range of MIC values seen in *in vitro* clones and clinical strains, it became obvious that the establishment of clinical breakpoints for BDQ/CFZ for *Rv0678* mutation harboring strains is very difficult [219]. Although a clear link has been established between *Rv0678* variants and failing BDQ/CFZ treatment regimens, it is not yet fully clear if the moderate increase in the MIC is rendering these drugs fully ineffective or if a change in drug dosing may be possible [159], [163], [222]–[224].

As was presented in this dissertation, Mtb strains with *Rv0678* mutations on average increased the MIC by 4-fold compared to the gWT ancestor for BDQ and CFZ. Since the WHO and other health authorities have not set efficacy targets for BDQ or CFZ clinical dosing [96], [225], continued treatment with CFZ and/or BDQ at a higher dosage may be a possible treatment option for Mtb strains harboring a *Rv0678* mutation. There are currently two clinical trials exploring BDQ dosing efficacy and safety [226], [227]. Still, further work is needed to fully elucidate clinical consequences and options for patients infected with Mtb strains harboring mutations in *Rv0678*. In the following section, this work aimed to elucidate the mechanism and phenotypic effects of these mutations by exploring their effect of bacterial fitness, the interplay with other co-selected variants, the selection of cross-resistant clones, and other potential genomic modifications.

5.3 Deciphering resistance mechanisms and their implications

In the previous section, it was shown that this sub-MIC evolution model selected a large diversity of resistance-associated variants for MFX, BDQ, and CFZ. Further, the potential of this model to predict clinically relevant resistance causing variants was demonstrated, as many of the mutations implicating the drug targets (*gyrA*, *gyrB*, and *atpE*) were described in patient-derived isolates. Indeed, this sub-MIC evolution model also captured the variability of mutations of the off-target gene *Rv0678*, in relation to BDQ and CFZ resistance. Next, several clones were selected which harbored the most important mutations (clinically relevant) and/or types of genetic modifications (missense mutations or indels) for additional analysis. Finally, further investigation was conducted exploring the diversity of resistance mutations throughout target and off-target genes, the rate at which CFZ exposure selected BDQ cross-resistant mutants, and novel resistance mechanisms.

5.3.1 The mutant selection window of resistance-associated mutations in bacteria of the *Mycobacterium tuberculosis* complex

One interesting question that has not been well addressed for major TB drugs is the definition of the MSW. This describes the drug concentration range between the MIC and the minimum selection concentration (the lowest concentration which the mutant outperforms the gWT) (Figure 2.5) [132]. To date, only one study performed in 2007 investigated the MSW with the Mtb reference strain H37Rv, performed *in vivo* with MFX [228]. There is a major knowledge deficit about the MSW, and better understanding can help optimize treatment regimens by defining the thresholds for potential harmful (non-inhibitory) drug concentrations.

In order to define the MSW, the growth capacity of H37Rv mutant clones with resistance-associated mutations to FQ (MFX) and BDQ were measured in the automated MGIT system, which detects oxygen consumption as an indication of growth. In the case of FQ associated variants, clones were evaluated which harbored the most common *gyrA* mutations observed in clinical isolates - D94G and A90V, also *gyrB* N499D, and the less common *gyrB* E501D. Four clones were evaluated with BDQ resistant phenotypes, two with an *atpE* mutation (E61D or D28V) [160], [211], and two clones with *Rv0678* mutations, the missense S68G and gene disrupting mutation R156_. The minimum selection concentration was extrapolated from the original evolutionary experiments, as resistant populations significantly increased when exposed to concentrations as low as 1:16 the MIC for all antibiotics tested (Figure 4.2.4, 4.2.5, 4.2.6).

These experiments demonstrated that the MSW starts far below the MIC. Indeed, as shown in the sub-MIC evolution model, comparably low drug concentrations of all antibiotics tested, selected mutant clones significantly. Interestingly, the MSW is variable between resistant clones with different mutations, even if mutations occur in the same gene at a different position (Figure 4.3.1, 4.3.2). For example, when analyzing the MSW of four MFX selected mutants, *gyrA* D94G outgrew *gyrA* A90V at antibiotic concentrations of 0.5 and 1.0 mg/L MFX, while D94G had a higher MIC of 2.0 mg/L compared to A90V of 1.0 mg/L MFX. Similarly, *gyrB* E501D exceeded the growth of *gyrB* N499D at 0.5 and 1.0 mg/L MFX, with MICs of 2.0 and 1.0 mg/L MFX respectively (Figure 4.3.1). However, when the same experiments were carried out with BDQ, clones with different variants had similar MSWs, where the MSW was more dependent on which resistance conferring gene was affected (Figure 4.3.2). Therefore, clones harboring different *Rv0678* mutations had the same MSW, and clones with *atpE* mutations had the same MSW. Indeed, the MSW of clones with *atpE* mutations appeared to be much larger than that for clones with a *Rv0678* mutation. However, the precise MSW of the *atpE* mutant clones was unclear, as both clones grew at the highest drug concentrations tested. These findings are especially important when drug combinations are designed and dosages of individual drugs are adjusted, in order to avoid favorable conditions for the selection of these variants. The next topic to explore was the effect of particular mutations on growth of the clones (fitness).

5.3.2 The fitness impact of resistance-associated variants

It has been established that resistance-associated variants can impact the fitness of Mtb strains [165], [182], [187]. It was hypothesized that the sub-MIC evolution model employed would select more clinically relevant, highly fit variants; since the weak selection pressure applied likely facilitated competition with the highly fit, susceptible gWT population and other resistant subpopulations [132], [165], [185]. This was partially verified as several of the resistance-associated mutations determined in the model were also detected in patient-derived Mtb isolates, either published or observed in the CRyPTIC strain collection [74], [159], [160], [163], [211]. Although clones with clinically relevant mutations were selected, it was not clear if these variants also impacted the fitness of the bacteria. Therefore, the relative fitness was evaluated through direct competition experiments, between the gWT ancestor and mutant clones, in antibiotic-free conditions.

Fitness experiments which measure the growth of one strain compared to another (typically compared to the gWT ancestor) are the gold standard for decoding fitness effects of unknown mutations [159], [164], [182], [229]. The same clones were investigated as with the MSW experiments (in the previous section).

In the case of FQ associated variants, virtually no fitness loss was linked to *gyrA* A90V and *gyrB* E501D variants. Similar results were also reported by Castro *et al.*, which investigated the same variants in different Mtb strains [182]. However, the clone which harbored *gyrA* D94G, presented a significant fitness defect as compared to the gWT ancestor. This is the most common resistance variant selected in these evolutionary experiments, and also observed in patient isolates. Therefore, it is surprising that a fitness defect was observed, but it could be that during FQ exposure these clones are more competitive.

Next, the competitive fitness was investigated between clones which were selected after BDQ exposure. Both clones with *atpE* mutations revealed a significant fitness loss, which contradicted the work of Huitric *et al.*, who showed Mtb strains with *atpE* variants do not exhibit a reduction in growth as compared to the gWT ancestor [201]. On the other hand, it was found that clones harboring *Rv0678* variants have various fitness levels, as the clone with the *Rv0678* S68G variant presented no fitness loss, and the clones with the gene disrupting mutation *Rv0678* R156_ had an average reduction in fitness. The fitness effects of *atpE* and *Rv0678* mutations have not been well examined, but these results contradicted Villellas *et al.*, who showed that a gene disrupting *Rv0678* mutation did not confer a loss of fitness in their Mtb strain [159].

Through direct competition experiments *in vitro*, it was shown that the fitness effects of mutations in resistance associated genes is variable between clones which harbor variants in different genes, but also the same gene at a different locus. Further fitness evaluation should be conducted in primary host cells (macrophages) and *in vivo*; as there may be a fitness effect in more complex biological systems. In the next section, it was questioned whether some clones acquired additional mutations, in genes not associated with resistance, which may affect the phenotype to a measurable degree.

5.3.3 Co-selection of off-target mutations

An important factor which has not been especially approached in *in vitro* selection models, are off-target mutations which might implicate bacterial fitness, tolerance, persistence, or other regulatory mechanisms. Typically, compensatory mutations are identified in large outbreaks of particular MDR-Mtb strains or genome-wide analysis studies, which comprise of thousands of strains [164], [188], [193], [194]. Although *in vitro* modeling is done to explore the phenotypic effect of these mutations, it is rarely done through *de novo* or stochastic evolution, but by genetic modification [164], [192], [230]. Therefore, it was investigated whether this sub-MIC evolution model also selected additional off-target mutations.

Off-target or “secondary” mutations were determined by comparing all alternative SNPs in non-reparative genes between the mutant and gWT ancestor genome. Of all the selected mutants, 84 harbored an additional mutation in a second gene, previously unrelated to resistance (Appendix D, Table D.1). In total, these included 20 different mutations affecting 20 different genes. The functional associations of these genes included cell wall processes, information pathways, metabolism & respiration, lipid metabolisms, and regulatory proteins; with at least six genes of unknown function. However, it is necessary to consider these may be hitchhiking mutations, which do not implicate the bacterial phenotype, a phenomenon also seen in patient-derived isolates [231]. To further investigate the possible clinical relevance of these variants, an inhouse collection of genome data of over 300,000 strains was screened for these off-target mutations. Unfortunately, there were no direct hits in patient-derived isolates. Since this search only included variants at specific positions in the genome, it is possible that one or more of these genes are clinically relevant, but that a different locus is implicated in patient-derived strains.

Although identical mutations were not detected in clinical Mtb strains, two clones with different off-target mutations were examined for their phenotypic effect. The first mutation was co-selected with an FQ resistance-associated variant. This mutant clone harbored the combination of the mutations *gyrA* A90V and *ppgK* _266S, the latter was a gene coding for a polyphosphate glucokinase enzyme associated with metabolism and respiration (Appendix D, Table D.1) [232]. When first looking at the MSW of these clones, the mutant with the secondary mutation appeared to have a slight growth advantage in higher drug concentrations compared to the clone lacking the mutation, although this was not significant (Figure 4.3.1). A second clone was investigated, which was resistance to BDQ/CFZ and harbored the mutations *Rv0678* S68G with the second mutation *mmpL5* A423D, a gene which codes for the efflux pump which the *Rv0678* protein regulates (Appendix D, Table D.1) [76]. The MSW of the off-target harboring mutant indicated a similar growth capacity as the clone with only the resistance-associated mutation (Figure 4.3.2). Direct competition experiments were also carried out with these clones. For both off-target mutation harboring clones, a statistical difference in their relative fitness (allele frequency) as compared to the pure resistant mutant was not observed (Figure 4.3.3, 4.3.4).

It was shown that this sub-MIC evolution model also selects variants with different off-target, secondary mutations. The two mutations explored through experimentation did not alter resistance, and were determined not to have a fitness effect. These variants could also have been selected by culturing, or simply as hitchhiking mutations. Although seemingly no phenotypic effect was attributed to these mutations, other experiments for a more dynamic evaluation should be conducted. One major pitfall of

the experiments performed here, is that they merely measured growth rate, but other functions should be explored like in-host survival, biological activity, and gene expression.

5.3.4 Cross-resistance between bedaquiline and clofazimine

Cross-resistance or collateral resistance occurs when a pathogen is able to gain resistance to at least two compounds from a single genetic mechanism. There are several instances in which genetic variants are linked with resistance to multiple drugs such as mutations in *rrs* to AMK, CPR, and KAN and in *inhA* to INH, PTH and ETH, to name a few (Table 2.1). Such events are especially concerning, since they can render an Mtb strain resistant to a drug before exposure, or reduce the effective treatment of combination therapies. Previous data already indicated that BDQ and CFZ have a cross-resistance mechanism via mutations in *Rv0678*, in which mutations can seemingly occur anywhere throughout the gene (Figure 4.2.10) [73], [163], [202]. Interestingly, all of these mutant clones presented an MIC increase to BDQ, regardless of drug exposure (CFZ or BDQ); but some mutants selected after BDQ exposure did not present an elevated MIC to CFZ (Appendix C, Table C.9). Therefore, the magnitude of cross-resistance between these two drugs was explored.

Indeed, most but not all mutations in *Rv0678* result in an elevated MIC to both BDQ and CFZ in the affected clone (Appendix C, Table C.9). As mentioned, all mutant clones selected after CFZ exposure were cross-resistant to both CFZ and BDQ, but some mutants selected after BDQ exposure were still phenotypically susceptible to CFZ. This indicated that cross-resistance with CFZ may be further linked mechanistically. It is hypothesized that SNPs in regions of the *Rv0678* gene affect protein stability and binding more prominently, when the mutations appear in the DNA binding region, protein stability, or dimerization domain [140], [233]. It is of concern that pre-exposure to CFZ fosters resistance to BDQ (the arguably more effective drug) before the strain has come into contact with BDQ. To investigate this experimentally, CFZ exposed cultures were plated on BDQ supplemented agar plates, and the resistant populations were quantified, as compared to BDQ exposed bacteria (Figure 4.2.7). Indeed, CFZ exposure is selected for BDQ resistant populations at a similar rate as BDQ exposure (Figure 4.2.8). Furthermore, the rate at which CFZ pre-selected BDQ resistant populations may be even higher than described, as these experiments were conducted retrospectively, from frozen stocks (stocks which were saved after sub-MIC evolution experiments conducted with CFZ), and likely a significant amount of the overall bacterial population was reduced during the freezing/unfreezing process.

Finally, a number of BDQ-CFZ selected clones were phenotypically resistant, with no genomic modifications in resistance-associated genes. These clones were further analyzed for special mechanisms of resistance.

5.3.5 Large scale gene rearrangement as a novel bedaquiline/clofazimine resistance mechanism

This study validated the important cross-resistance mechanism for BDQ and CFZ by genomic modification of the *Rv0678* gene, which other studies have found to influence *mmpS5-mmpL5* efflux pump expression [73], [140], [202]. For the majority of clones selected after this study's sub-MIC evolution experiments, mutations in *Rv0678* or in *atpE* could be identified as the likely resistance mechanism. Still, 13 clones which were randomly selected from BDQ and CFZ supplemented agar plates, did not harbor a mutation in any of the defined resistance-associated genes (Table 4.3.1). Nine of the thirteen clones had at least one variant in other regions of the chromosome (off-target mutations). To further decipher possible resistance mechanisms in these clones, IGV software was used to look into the genome alignment of BDQ/CFZ resistance-associated genes (Figure 4.3.5). Interestingly there was an unusual coverage signal in the *Rv0678* gene coding region, which indicated a large structural modification (Figure 4.2.11). Large structural modifications, large indels, and duplicated genes are not yet picked up by most short-read sequencing computational pipelines. Therefore, three of these clones were selected for PacBio® long-read sequencing and *de novo* assembly.

After *de novo* assembly, a 2.7 Mb inversion flanked by the transposable element insertion sequence *6110* (*IS6110*) was identified. This inversion is the largest known gene rearrangement in *Mtbc* to date, and the first to be spontaneously developed *in vitro* and implicated in drug resistance. Due to the special nature of this finding, the sequencing data was sent to colleagues at Cambridge University (by Z. Iqbal, K. Malone, and M. Hunt) for further analysis. The original conclusion was verified, and these external reviewers reported one similar instance in their patient strain collection.

There have been a few studies which demonstrated similar large-scale gene rearrangements in *Mtbc* clinical isolates. For example, Saw *et al.* observed large and small-scale rearrangement in proline-glutamate/proline-proline-glutamate (PE/PPE), membrane, and transcriptional genes in strains isolated from cerebrospinal fluid [139]. Shitikov *et al.* also presented a large-scale chromosomal rearrangement in a Beijing outbreak, although again it was not linked to resistance [138]. Both of these studies also found flanking of *IS6110*, a sequence used in DNA fingerprinting for *Mtbc* strain typing [234], [235]. Detection of

structural variations is not routinely integrated in TB genomic research pipelines, likely due to the overwhelming consensus that the *Mtbc* genome is incredibly stable. Although transposition of these sequences is rare, this and other studies might point at the importance of insertion sequences (or specifically *IS6110*) and repetitive regions (*PE/PPE* genes) in *Mtbc* polymorphisms and evolution [138], [139], [235].

In conclusion, the data obtained here showed that large rearrangements in the *Mtbc* genome can be involved in drug resistance development and thus, represent important genetic information that need to be deciphered for genomic resistance prediction workflows.

5.5 Conclusion

Taken together, this work highlighted the adaptive evolutionary landscape of Mtb bacteria through intra-patient evolution of a single strain, *in vitro* sub-MIC evolution model, and a large strain collection examination. Indeed, resistance evolution of Mtb bacteria is highly dynamic, and more diverse than previously thought. By investigating an Mtb strain evolution throughout a failing MDR-TB therapy, it was shown that resistance evolution is an arms race between heteroresistant subpopulations that is fuelled by inappropriate drug regimens. This study successfully established a sub-MIC long-term evolution model that allowed for effective isolation of resistant mutant clones as a basis for establishing variant catalogues for genomic resistance prediction. Using the sub-MIC evolution model, a large collection of *de novo* mutants with an available gWT ancestor for FQs, BDQ and CFZ was established for future research. This model also demonstrated for the first time that resistant clones can be selected in an environment with a weak selection pressure far below the MIC. The mutant selection window for the main MDR-TB drugs is wider than previously anticipated indicating that sub-inhibitory concentrations, e.g. caused by structural constraints in infected organs, can lead to resistance selection and treatment failure. The data obtained also demonstrated that the majority of mutations in *Rv0678* confer cross-resistance to BDQ and CFZ, and that CFZ exposure selects for mutant populations also resistant to BDQ. Finally, the data obtained was also used to establish a comprehensive mutational catalogue for genotypic, drug resistance prediction for BDQ/CFZ. This study progresses the field of research on resistant TB by introducing an evolution model for antibiotic and resistance screening. By incorporating this information into sequencing-based diagnostic approaches, better treatment therapies can be designed for highly resistant cases, which in the end might help control the spread and evolution of resistant strains.

Still, future questions arose that could not be fully addressed in the current work. Further experiments should be conducted to:

- elucidate functional differences between resistance-associated variants in patient-derived isolates
- additional evaluation of phenotype/fitness of *in vitro* selected mutations - through more competition experiments, measuring growth and infectability of macrophages, and survivability in an *in vivo* model
- understanding of resistance mechanisms observed - like investigating the transcriptional effect of SNPs vs indels in *Rv0678* mutants on the expression of the *mmpS-mmpL* efflux pump
- analyze the MSW for other drugs currently applied in TB treatment and for new drug candidates that are developed

9. Abbreviations

–	stop codon
a	adenine
AA	amino acid
alt.	alternative
AMC	amoxicillin + clavulanic acid
AMK	amikacin
BCG	bacillus Calmette-Guerin
BDQ	bedaquiline
bp	base pair
c	cytosine
CFU	colony forming unit
CFZ	clofazimine
CLR	clarithromycin
conc.	concentration
CPR	capreomycin
CRyPTIC	Comprehensive Resistance Prediction for Tuberculosis: an International Consortium
CS	cycloserine
CTAB	hexadecyltrimethylammonium bromide
del	deletion
DLM	delamanid
DNA	deoxyribonucleic acid
DOTS	directly observed treatment, short-course
DST	drug susceptibility testing
EMB	ethambutol
et al	"and others"
ETH	ethionamide
FQ	fluoroquinolone
fs	frameshift
g	guanine

GFX	gatifloxacin
gWT	genetically wild-type
i.e.	id est "in other word"
indel	insertion or deletion
INH	isoniazid
ins	insertion
IS6110	insertion sequence 6110
KAN	kanamycin
LFX	levofloxacin
LZD	linezolid
MDR	multidrug resistant
MFX	moxifloxacin
MGIT	mycobacterium growth indicator tube
MIC	minimum inhibitory concentration
MSC	minimum selection concentration
MSW	mutant selection window
Mtbc	<i>Mycobacterium tuberculosis</i> complex
NA	not applicable
NGS	next generation sequencing
ns	not significant
NT	nucleotide
OD	optical density
OFX	ofloxacin
OP	out-patient
PAS	para-aminosalicylic Acid
PCR	polymerase-chain reaction
PE/PPE	proline-glutamate/proline-proline-glutamate
PRT	pretomanid
PTH	prothionamide
PZA	pyrazinamide
QRDR	quinolone resistance determining regions
RBT	rifabutin

rcf	relative centrifugal force
ref.	reference
REMA	resazurin emission microtiter assay
RIF	rifampicin
RNA	ribonucleic acid
RR	rifampicin-resistant
rRNA	ribosomal RNA
RT	room temperature
Subs	substitutions
SDS	sodium dodecyl sulphate
SFX	sparfloxacin
SM	streptomycin
SNP	single nucleotide polymorphisms
t	thymine
TB	tuberculosis
TRD	terizidone
WGS	whole genome sequencing
WHO	World Health Organization
XDR	extensively-drug resistant

Appendix A

Introduction supplementary materials and extended data

Table A.1 Distribution of tuberculosis drugs throughout the granuloma and lung cavitation. Drug concentrations below (low), less than (med), or at or above (high) the critical concentration.

Granuloma

Drug	Plasma/ blood	Fibrous cuff	Cellular layer	Caseum	Intra-macrophage
INH	high [†] [114]	low [*] [112]	med [*] [112]	high [†] [114]	low [*] [112]
RIF	low [†] [114]	high [*] [112]	med [*] [112], high [†] [114]	none [*] [112], low [†] [114]	low [*] [112]

Appendix B

Supplementary Material and extended tables of Results 4.1

Table B.1: Patient treatment history, including phenotypic drug resistance testing, over five TB treatment episodes. Phenotypic resistance/susceptibility was reported by several diagnostic labs throughout Germany, including Research Centre Borstel. Once a resistant phenotype was reported regular testing may not have been repeated, thus the phenotypic results at given intervals are not completely comprehensive. Emerging genotypic resistances were predicted for 13 available patient-derived isolates; date of collection indicated by months since the start of therapy “Therapy (month)”.

Therapy (month)	Hospital	Treatment Regimen	Clinical notes	Phenotypic Resistance	Phenotypic Susceptibility	Genotypic Resistance	Active drugs in treatment by genotype	Active drugs in treatment by phenotype
1st TB Episode								
1-4	1	INH, PAS, SM [†] , tyloxapol [‡]						
No TB symptoms - 17 years								
2nd TB Episode								
1	2	INH, EMB, SM						
2-4	3	INH, RIF, EMB	Culture negative					
No TB symptoms - 1 year								
3rd TB Episode								
1-6	4	INH, RIF, SM	Cavities in left and right upper lobes					
7-41	OP	INH, RIF, SM	No bacilli detected					
No TB symptoms - 8 years								
4th TB Episode								
1	-	PZA, SM, TRD	Bacilli detected and lung cavitation observed					
1-3	5	INH, RIF, EMB, PZA, CPR						

Therapy (month)	Hospital	Treatment Regimen	Clinical notes	Phenotypic Resistance	Phenotypic Susceptibility	Genotypic Resistance	Active drugs in treatment by genotype	Active drugs in treatment by phenotype
4	5	INH, RIF, EMB, PAS	Culture positive	(month 4) INH, EMB, PZA, PTH, SM	(month 4) RIF, PAS

*Phenotypic test was considered for "Active drugs in treatment" as no genotypic markers are available for these drugs (CLR and AMC)

[†]Treated with dihydrothenat, a SM derivative

[‡]tyloxapol is an anti-mucosal

^b border-line resistance (often viewed as some bacterial growth but below or on the border of the resistance threshold)

AMK - amikacin, AMC - amoxicillin+clavulanic acid, CFX - ciprofloxacin, CFZ - clofazimine, CLR - clarithromycin, CPR - capreomycin, CS - cycloserine, EMB - ethambutol, FQ - fluoroquinolone, INH - isoniazid, KAN - kanamycin, LZD - linezolid, MFX - moxifloxacin, OP - out-patient, PAS - para-aminosalicylic acid, PTH - prothionamide, RIF - rifampicin, RBT - rifabutin, SM - streptomycin, SFX - sparfloxacin, TRD - terizidone, Z - pyrazinamid

Table B.2: Population frequency of resistance, compensatory, and tolerance associated mutations. Thirteen serial isolates were collected in the final treatment episode of an MDR turned XDR-TB infection. Frequency was calculated from whole genome sequencing data, as the percentage of alternative allele reads. High-confidence mutations, indicated in bold font, were predicted to have an effect on phenotype.

Appendix C

Supplementary Material and extended tables of Results 4.2

Table C.1 Generation time of H37Rv lab strain. Generation time was calculated for each evolutionary experiment, from the first culture passage of the antibiotic free control.

$$\text{Generation time} = \text{Total hours} \div \left(\frac{\log(CFU_{final})}{\log(CFU_{start})} \div \log(2) \right)$$

Experiment	CFU inoculum	Growth time (hours)	Final CFU	Generations	Generation time (hours)
1	1.16×10^7	95	1.45×10^8	3.6	26.1
2	1.11×10^7	95	1.22×10^8	3.3	28.6
3	8.59×10^6	96	1.31×10^8	3.9	24.4
4	6.16×10^6	98	2.25×10^8	5.2	18.9
5	2.50×10^7	97	1.18×10^8	2.2	43.4
6	1.58×10^7	97	1.43×10^8	3.2	30.6
7	3.17×10^7	96	2.41×10^8	2.9	32.8
8	2.65×10^7	96	2.13×10^8	3.0	32.0
9	2.09×10^7	96	1.74×10^8	3.1	31.4
Average:				3.4	29.8
Standard deviation:				0.8	6.7

CFU - colony forming unit

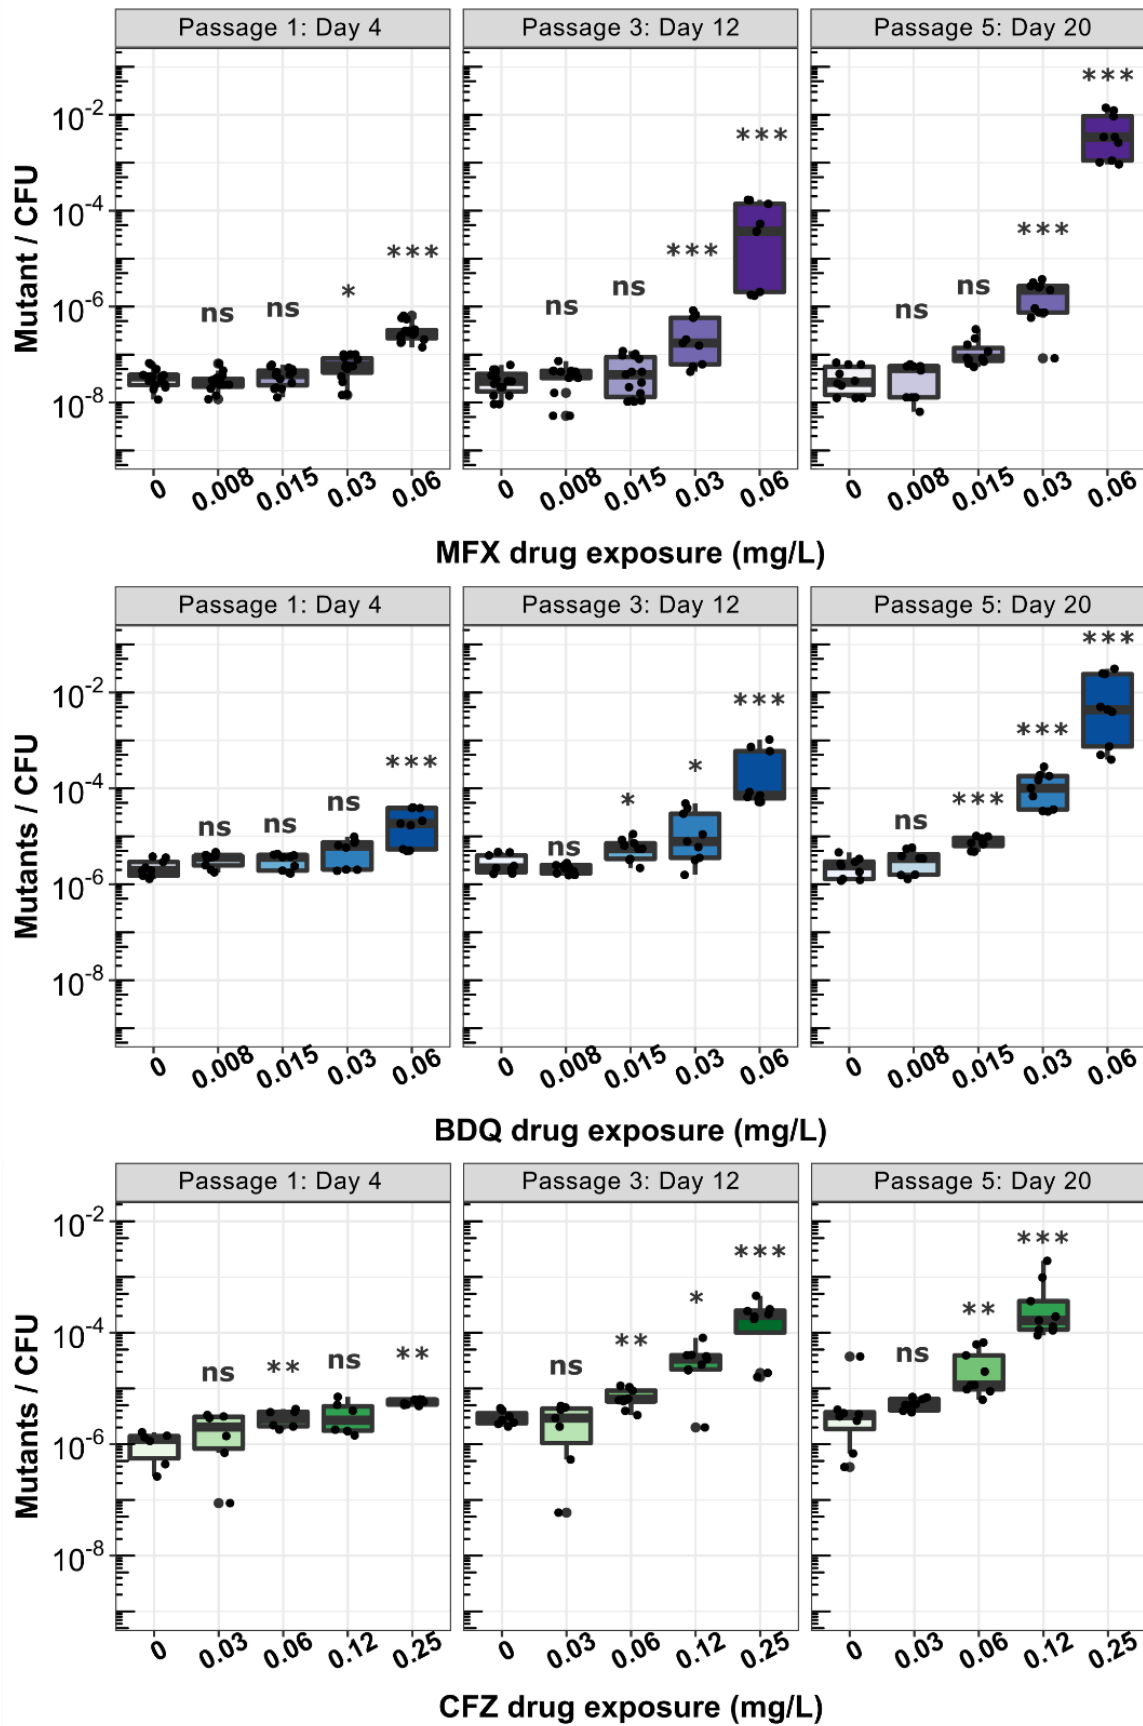

Figure C.1: Mutant enrichment after sub-inhibitory drug exposure; mutants per total colony forming units. The *Mycobacterium tuberculosis* complex lab strain H37Rv was exposed sub-inhibitory concentrations of either (A) moxifloxacin (MFX), (B) bedaquiline (BDQ), or (C) clofazimine (CFZ); concentrations between 1:2 to 1:16 below the strain minimum inhibitory concentration (MIC). The bacteria were exposed to the antibiotic for 20 days, consisting of five culture passages. Bacterial samples were evaluated at three time points during the experiment, after day 4 or “passage: 1”, day 12 “passage: 3”, and day 20 “passage: 5”. The cultures were plated on 7H10 agar plates for CFU counting for bacterial quantification, additionally cultures were plated on 7H10 (for MFX) or 7H11 (for BDQ or CFZ) plates supplemented with antibiotic at the critical concentration (0.25 mg/L MFX), or the strain MIC (0.12 mg/L BDQ, 0.5 mg/L CFZ). Mutant enrichment was calculated as the number of colonies / mL counted on antibiotic supplemented media divided by the total CFU per mL (number of colonies on selected media divided by colonies counted on antibiotic free media).

Statistics: Three independent experiments were conducted with 1 biological replicate per experimental condition, with 3 to 5 technical replicates each. Statistics were calculated as nonparametric multiple contrast test (Kruskal) with a confidence interval of 95%, p-values between drug exposed and the antibiotic free control (0 mg/L of antibiotic): *p<0.05, **p<0.01, ***p<0.001

Table C.2: P-values of evolutionary experiments, colony forming units, and mutant enrichment. Colony forming units (CFU) of each experimental condition were compared to the antibiotic free control in the corresponding experiment. Each statistical test was conducted using R studio, see Appendix E.

MFX - CFU

Passage	Cont. - 0.008mg/L	Cont. - 0.015mg/L	Cont. - 0.03mg/L	Cont. - 0.06mg/L

BDQ - bedaquiline, CFU - colony forming unit, CFZ - clofazimine, Cont. - control, MFX - moxifloxacin

Table C.3: P-values of cross-resistance comparison between bedaquiline and clofazimine selection of bedaquiline mutants. Comparison of bedaquiline (BDQ) resistant mutant populations (mutants/million colony forming units; CFU), recovered after BDQ or clofazimine (CFZ) exposure. Populations were compared between concentrations relative to the MIC (1:16, 1:8, 1:4, 1:2, and no antibiotic), and corresponding exposure time (passage 1, 3, or 5). Each statistical test was conducted using R studio, see Appendix E.

Passage	BDQ control vs. CFZ control	1:16 MIC BDQ vs. 1:16 MIC CFZ	1:8 MIC BDQ vs. 1:8 MIC CFZ	1:4 MIC BDQ vs. 1:4 MIC CFZ	1:2 MIC BDQ vs. 1:2 MIC CFZ
1	9.55×10^{-2}	0.002	0.010	0.116	8.85×10^{-2}
3	0.32	0.57	0.042	0.999	0.336
5	0.94	0.999	0.999	0.877	6.18×10^{-10}

Table C.4: Next generation sequencing statistics of deep sequencing run with moxifloxacin exposed bacterial populations.

AA - amino acid, Alt. - alternative, BDQ - bedaquiline, CFZ - clofazimine, Del - deletion, gWT - genetically wild-type, Ins - insertion, MIC - minimum inhibitory concentration, NA - not available, NT - nucleotide, Ref. - reference, _ - stop codon

Table C.10 Genomic summary of CRyPTIC strains with variants in bedaquiline/clofazimine resistance-associated genes. Patient isolates collected by Comprehensive Resistance Prediction for Tuberculosis: An International Consortium partners (CRyPTIC) and interpreted by Joshua Carter (Yale University, CRyPTIC member). List includes only minimum inhibitory concentration verified isolates (to at least bedaquiline; BDQ) in UKMYC5/6 broth microtiter plates.

BDQ - bedaquiline, CFZ - clofazimine, CRyPTIC - Comprehensive Resistance Prediction for Tuberculosis: An International Consortium, DST - drug susceptibility testing, ID - identification, MIC - minimum inhibitory concentration, SNP - single nucleotide polymorphism

Table C.11 Catalogue of mutations in bedaquiline and clofazimine resistance-associated gene in bacteria of the *Mycobacterium tuberculosis* complex. Resistant, borderline and susceptible variants found in bedaquiline (BDQ) and clofazimine (CFZ) resistance-associated genes. Table includes mutations defined in the *in vitro* and patient isolate datasets, plus a literature review of all resistance-associated variants detected in clinical isolates, *in vitro* and *in vivo* isolates. Adapted from Sonnenkalb *et al.* 2021 [140].

Minimum inhibitory concentration was determined by: [A] BD-MGIT™, [B] UKMYC5/UKMYC6 plates, [C] Alamar blue/resazurin assay, [D] 7H10 plates, [E] 7H11 plates

Resistant (R), borderline (B), and susceptible (S) phenotype was defined by test of study as: [A] 1mg/L BDQ/CFZ [96]; [B] 0.12-0.25mg/L BDQ/CFZ [238], [C] defined by study authors, [D] 0.5mg/L BDQ [239]/CFZ [240], [E] 0.25 mg/L BDQ [96] -CFZ determined by study authors

Alt. - alternative, B - borderline, BDQ - bedaquiline, CFZ - clofazimine, del – deletion, DST - drug susceptibility testing, fs – frameshift, ins – insertion, IS6110 - insertion sequence 6110, NA – not available, R - resistant, Ref. - reference, S - susceptible, SNP – single nucleotide polymorphism, _ – stop codon insertion

Appendix D

Supplementary Material and extended tables of Results 4.3

Table D.1 Off-target mutations co-selected with resistance-associated mutations after *in vitro* evolutionary experiments. All mutations were present in clones at a frequency >98%, with no additional mutations detected, as compared to the wild-type ancestor strain. Clones with more than one off-target mutation were not included.

Figure D.1: Mutant selection window of bedaquiline resistance mutations. Resistance-associated mutations *atpE* A63P, *atpE* D28V, *Rv0678* R156_, and *Rv0678* S68G were isolated from BDQ evolutionary experiments. Each mutant clone was separately cultured in Mycobacterium growth indicator tubes (MGIT) and growth was measured hourly, until time to positivity (fluorescence signal measured greater than or equal to 400 units) was achieved. Data is representative of two independent experiments, with a total of five biological replicates.

Appendix E

Statistics

All statistical tests were performed as non-parametric Kruskal-Wallis test, computed in R statistical program. R-script as follows:

```
##Statistical Test##

head(mfxfit)

# Show the group levels

levels(mfxfit$mutation)

# Compute summary statistics by groups

library(dplyr)

group_by(mfxfit, mutation) %>%

  summarise(

    count = n(),

    mean = mean(freq_change, na.rm = TRUE),

    sd = sd(freq_change, na.rm = TRUE),

    median = median(freq_change, na.rm = TRUE),

    IQR = IQR(freq_change, na.rm = TRUE)

  )

kruskal.test(freq_change ~ mutation, data = mfxfit)
```

Acknowledgments

Without the help and dedication of many colleagues, family, friends, and people; this dissertation would not have been possible.

First, I would like to thank my supervisor **Prof. Dr. Stefan Niemann**. Stefan is truly an amazing researcher and scientist, who has an uncanny ability to develop projects and collaborations which I did not know was possible. I am very lucky that I had the ability to work with and learn from such a person. More so, I am so grateful that Stefan is easy to talk to, get along with, drink a beer with, and someone who loves people and wants to help the world. Most of all Stefan has been an incredible mentor to me, and provided me with so many opportunities and support in my career that I am forever grateful. I hope that I can emulate his style of supervision one day.

I would next like to thank my junior supervisor **Prof. Dr. Matthias Merker**, for his dedication to my project, especially the endless, invaluable intellectual and creative advice. Matthias really put countless hours into helping me succeed – from experimental designs, correcting my writing/presentations/reports, teaching me how to use different computational programs, helping with figure design, and the list goes on. But Matthias was also a kind person who provided me with an optimistic and realistic view of the scientific profession (and especially the world of publishing), and just a decent person to everyone. I hope that I can also emulate his style of supervision one day.

Also, a special thank you to **Prof. Dr. Torsten Goldman**, who as a co-supervisor offered me additional mentoring support and was also a kind person to sit with and enjoy a coffee. Torsten gave me really wonderful advice and reassurance which I really appreciated.

A number of my colleagues I would also like to acknowledge for their additional technical support such as **Ivan Barilar** who helped me with various analyses in this study, **Dr. Patrick Beckert** who was the most welcoming person and a great lunch time companion. To **Dr. Viola Dreyer**, an amazing mathematician who not only helped me analyze my data with the binoSNP tool she developed, but made time to help me with my statistical and various analyses. Also, **Dr. Christian Utpatel** who especially helped me with the PacBio® analysis. Finally, to **Dr. Susanne Homolka**, **Dr. Sven Malm** and **Dr. Silke Feuerriegel**, who gave me valuable input when designing my experiments, especially in the beginning of my thesis work.

I want to thank **Dr. Christiane Gerlach**, not only was she the project manager for EvoLUNG, but also an amazing group member who was always kind and patient with me. She is a person who really listens when you are talking and has a love for science which I find very inspiring.

Next, I want to give a special thank you to my dear friend and EvoLUNG colleague **Jessica Ojong**, for her help and kindness. Jessica has been an inspiration to always do my best, and she provided me with stimulating scientific conversation and helpful advice related to my work.

I want to thank all of the **EvoLUNG team**, but especially for the help and input from **Prof. Dr. Heinrich Schulenburg** and **Dr. Leif Tüffers**, who were wonderful to talk with and share ideas, but also gave me important mentoring for my project and future scientific career.

A number of post-doctoral researches in the Molecular and Experimental Mycobacteriology group have been also wonderful and helpful throughout my work including **Dr. Thomas Kohl**, **Dr. Judith Petersen**, **Dr. Meriem Belheouane**, and **Dr. Margo Diricks**.

I had further help from colleagues at the National Reference Center for Mycobacterium in Borstel, such as performing diagnostic tests, selecting strains, and collaborating on my first paper. Thank you so much **Dr. Sönke Andres**, **Dr. Doris Hillemann**, and **Dr. Florian Maurer**. Also, thank you to the technical support from **Ilse Radzio** and **Anne-Katrin Witt**.

I want to give a huge appreciation and thank you to the technicians in my group, especially **Doreen Beyer** and **Silvia Maaß** who gave me all my initial laboratory training and helped me with large experiments. To **Carina Hahn**, **Ménie Wiemer**, and **Larissa Mohr** for their help in the biosafety level 3 laboratory. Also, to **Anja Lüdemann** and **Tanja Struve-Sonnenschein** for their help in the molecular lab and training me in DNA isolation. Last but not least, a big big thank you to **Fenja Boysen**, **Vanessa Mohr**, and **Tanja Niemann** for their help and training in library preparation and next generation sequencing.

To the doctoral students in my group, a big thank you for your help, support, and ideas. But an even bigger thank you for just being an awesome group of people who were wonderful to share an office with and spend time with outside of work: **Harriet Blankson**, **Johanna Perez-Llanos**, **Emilie Rousseau**, **Jana Schönfeld**, **Dr. Yassir Shuaib**, and **Teresa Waltz**. With an extra special thank you to **Dr. Matthias Gröschel** who is an amazing scientist and gave me invaluable tips to improve my experiments.

Further help from people outside of Research Center Borstel included **Dr. Claudio Köstner** who gave intellectual contributions and project collaborations, to **Dr. Gerald Strohe** for collecting and sharing data for my first publication.

To my colleagues in the CRYPTIC consortium for their help with analysis, writing of our collaborative paper and sharing strains for my second publication – **Dr Andrea Spitaleri** and **Prof. Dr. Daniela Cirillo** from IRCCS San Raffaele Scientific Institute; **Prof. Dr. Zamin Iqbal**, **Dr. Kerri Malone**, and **Dr. Martin Hunt** from the

European Bioinformatic Institute in Cambridge; and especially **Joshua Carter** and **Prof. Dr. Philip Fowler** for their extensive work on our collaboration. Further I want to thank all **CRyPTIC** partners for their hard work on an amazing project and advancements in molecular and phenotypic diagnostics for detecting drug resistant TB.

I want to thank my friends. Some of whom contributed intellectually to my work, but mostly for helping keep me sane - **Sarah Thom-Carter, Clint Carter, Sandra Júkic, Ombretta Colasanti, Laura Lollman, Joshua Lollman, Nicole Moreno, Dr. Christina Rau, Jason Rau, Antonio Rivera, Aracelli Rivera, Chelsea Rivera, Simone Tazoll,** and **Jacqueline Wax**. But especially to **Iretiolu Ogunsulire** and **Denise Ohnezeit** who even read my thesis and gave me awesome input.

I want to also give a special thanks to the funding entities for whom none of this work would have been possible, thank you for taking the risk on these projects – Evolutionary Medicine of the lung (EvoLUNG), Research Center Borstel Leibniz Lung Center, Christian-Albrechts-Universität Kiel, Max Planck Institute for Evolutionary Biology, Leibniz Gemeinschaft, and Schleswig-Holstein.

Finally, I would like to thank my family **Jim Tucker, Carla Tucker, James Tucker** and **John Tucker** for their encouragement, love, and financial/emotional support. And a big thank you to my German family **Elisabeth Sonnenkalb, Jürgen Sonnenkalb, Nikolas Sonnenkalb,** and **Mari Hase** for their love and support. Thank you to my little angel **Klaus**, without any formal training he is an outstanding emotional support animal.

Last but not least, I want to thank my husband **Roman Sonnenkalb**, without him I would not have had the strength to attempt such an endeavor. Thank you so much for your love and understanding, for keeping me sane and well fed. I love you forever and always.

List of Publications

M. Merker, L. Tueffers, M. Vallier, E. Groth, **L. Sonnenkalb**, D. Unterweger, J. Baines, S. Niemann, H. Schulenburg “Evolutionary Approaches to Combat Antibiotic Resistance: Opportunities and Challenges for Precision Medicine,” *Frontiers in Immunology*, vol. 11, p. 1938, 2020, doi: 10.3389/fimmu.2020.01938.

Status: published

L. Sonnenkalb, G. Strohe, V. Dreyer, S. Andres, D. Hillemann, F. Maurer, S. Niemann, M. Merker “Microevolution of *Mycobacterium tuberculosis* hetero-resistance subpopulations in a patient receiving 27 years of tuberculosis treatment in Germany,” *Antimicrob Agents Chemother*, Jun. 2021, doi: 10.1128/AAC.02520-20.

Status: published

L. Sonnenkalb, JJ. Carter, A. Spitaleri, Z. Iqbal, M. Hunt, K. Malone, C. Utpatel, DM. Cirillo, C. Rodrigues, KS. Nilgiriwala, CRYPTIC, PW. Fowler, M. Merker, S. Niemann “Deciphering Bedaquiline and Clofazimine Resistance in Tuberculosis: An Evolutionary Medicine Approach,” *bioRxiv*, p. 2021.03.19.436148, Mar. 2021, doi: 10.1101/2021.03.19.436148.

Status: in review

List of Presentations

Keystone Conference: Tuberculosis – April 2018 – Whistler, CA

Poster: Intra-patient *Mycobacterium tuberculosis* strain dynamics – A 12-year M/XDR- TB treatment history

European Society of Mycobacteriology – June 2018 – Dresden, DE

Oral: Antibiotic resistance evolution of *Mycobacterium tuberculosis* – A 57-year M/XDR- TB treatment history

2nd Joint Congress of Evolutionary Biology – August 2018 – Montpellier, FR

Poster: Intra-patient *Mycobacterium tuberculosis* strain dynamics – A 18-year M/XDR- TB treatment history

International Society of Evolutionary: Medicine and Public Health - August 2019 – Zurich, CH

Oral: Antibiotic resistance evolution of *Mycobacterium tuberculosis* complex bacteria, during sub-lethal drug exposure

Join annual meeting DGI-DZIF – November 2019 – Bad Nauheim, DE

Poster: Antibiotic resistance evolution of *Mycobacterium tuberculosis* complex bacteria during sub-lethal moxifloxacin and bedaquiline exposure

International Symposium: Precision Medicine in Chronic Inflammation –

February 2020 – Hamburg, DE

Poster: Sub-lethal exposure drives resistance evolution in *Mycobacterium tuberculosis* complex bacteria
